The implementation of geriatric oncology into clinical practice can be complex; therefore, direct counseling and advice is often needed. The Association of Community Cancer Centers (ACCC) developed a library of resources to simplify access to the geriatric oncology tools.[45] In addition, the gap assessment tool created by the ACCC on the basis of input from cancer and aging experts allows health care professionals to evaluate and improve their cancer and aging practices by providing an individualized assessment of each of the tools they use and offers recommendations on the basis of best practices.[46] Another resource is the Clinical Implementation Core (CIC) established by the Cancer and Aging Research Group (CARG) to facilitate the dissemination of geriatric oncology evidence-based principles.[47] The primary function of the CARG CIC is to provide health care professionals with guidance regarding the clinical integration of geriatric practices into oncology care and providing support with program development, business model design, and strategic planning.[48]

Additional challenges commonly encountered by health care providers interested in developing a cancer and aging program include identifying and gathering resources to be able to support the implementation of a clinic. A good understanding of the resources available at the local level that could be used to support the clinical operation is a primary component of such a structure. The design of the

geriatric oncology practice should match the available resources otherwise the durability of the program is likely to be at risk. In addition, it should consider the priorities of the geriatric oncology service consumers: patients, caregivers, providers, and the institution. Understanding the health care context in which the proposed program will operate is critical. Specific questions should address (1) the priorities and pressures in the system, (2) the availability of geriatricians and other health care professionals, and (3) physician payment models. In some instances, understanding the political climate and appetite for improving care of older adults can also be helpful when developing strategies to garner resources for an aging and cancer program.

Having a thorough understanding of the opportunities and barriers in one's particular context is an important first step in successfully developing and implementing a cancer and aging program.

DEVELOPING A PROPOSAL FOR A CANCER AND AGING PROGRAM

Making a Case for Stakeholders

The critical first step in the development and deployment of a geriatric oncology model of care is the identification of a physician champion, who is passionate, is committed, and will lead the charge. This individual will need to perform a strategic stepwise stakeholder assessment to best understand the local landscape. Proposals spearheaded by geriatrics should seek to build alliances with oncology and vice versa. Building a coalition of clinicians, health care professionals, and administrators interested and passionate about improving care of older adults with cancer is critical to the development of a cancer and aging program, its successful implementation, and its ongoing success.

Selecting and Developing a Cancer and Aging Program Model

An assessment of locally available resources should be undertaken, including health care personnel with expertise and interest in the care of older adults with cancer. This assessment can then inform the potential model of care delivery (primary geriatric oncology, consultative, or embedded model). An estimate of the number of patients who will be seen and affected by the implementation of a cancer and aging program is important to ascertain and include in the proposal. The capacity of the proposed program will also help guide how patients are identified (age and screening tool) and referral criteria.

Development of a Business Case

The next important step is to develop a business case to present to the local leadership. Key members of the leadership team may include the cancer center director, department/division chairs, administrators from the health system and/or cancer center, and physicians/care team members in the department and/or practice. The business plan will need to address several facets, some of which may be more or less relevant depending on the particular health care context. These include (1) current and future resources needed to develop and grow the program including specific metrics of success, (2) impact of the program on clinical growth/patient care retention, (3) research opportunities, (4) educational and training pipeline opportunities, (5) philanthropy needs and/or opportunities, and (6) additional programmatic development including survivorship and supportive care and specialty specific programs such as cardio-oncology, psycho-oncology, and cancer rehabilitation medicine, all of which can serve to support care of older adults with cancer.

An important part of the discussion with leadership should include the rationale for developing the cancer and aging program and the expected impact of the program. Understanding the priorities of the cancer center and those leading the cancer program and/or geriatrics can be helpful to align messaging about potential benefits of a cancer and aging program. These include outcomes of improving quality, safety, and eliminating disparities in care for the community served by the cancer center, health system, or practice, and the importance the program will have to elevate and differentiate the care provided. Certainly, there are strong data from multiple randomized controlled studies that have shown a decrease in treatment-related toxicity and hospitalizations and an increase in the likelihood of completion of chemotherapy.[17-19,25] From a surgical perspective, one study suggested that GA may lead to decreases in length of stay and intensive care unit (ICU) admissions.[27]

Ensuring the financial feasibility of a new program is extremely important. Showcasing the potential to decrease costs and/or the potential to offset initial investments into the program is important messaging when making a business case for a cancer and aging program. Decreased visits to the hospital and/or hospital admissions because of toxicity can lead to decreased costs to the hospital or health system. Pretreatment GA may also result in change in treatment plans (eg, decision against surgery, change in planned systemic therapy, and decision for best support care). This process can result in considerable cost savings with one study demonstrating a cost saving of almost $7400 Canadian dollar (CAD) per patient assessed, for a net saving of $1.1 million CAD.[49]

Keys to Successful Implementation

Once approved, there are several key factors that can help promote successful implementation of the proposed cancer and aging program. Starting with small-scale changes, creating visible early successes, and building on these can help facilitate and accelerate the implementation process.

A geriatric oncology practice is most likely to succeed if it is not considered intrusive by the consumers and if it does not overwhelm the daily clinical operation. A start low and go slow approach can be extremely beneficial to those building geriatric oncology programs as it allows them to test their resources and modify their approach in a more flexible environment by focusing initially on a smaller implementation scale such as a specific older patient population and/or practice location. In addition, this strategy creates an environment that increases the likelihood of demonstrating success, which is critical at the early stages of implementation, especially when considering the importance of gathering the support at the local level through all disciplines and across all levels of leadership. Building a clinical practice on the basis of this stepwise strategy is likely to require fewer resources at inception and is less dependent of significant initial funding. As the program develops and meets defined metrics, further acquisition of resources should be more easily justified to leadership to facilitate growth.

GERIATRIC ONCOLOGY IN THE HIGH-RESOURCE SETTING: NATIONAL CANCER INSTITUTE–DESIGNATED CANCER CENTERS

Insight from the success of the French Geriatric Oncology National System[50] which aligns clinical and research efforts in a structured model of government-supported geriatric oncology centers would suggest that significant opportunity exists through National Cancer Institute (NCI)–designated cancer centers in the United States to advance the field of geriatric oncology with breakthrough discoveries relevant to older adults with cancer leading to paradigm shifts in the care delivered.

Highly resourced NCI-designated cancer centers have the infrastructure necessary to foster the development of state-of-the-art comprehensive geriatric oncology programs to reduce the cancer burden throughout their respective catchment areas and collectively on a national level. Bridging basic, translational, and population science efforts and linking this to training and education and clinical care delivery will enable unique breakthrough discoveries, that address the specific needs of older adults with cancer, to be moved from the bench to the community and beyond. Emphasis on standardized geriatric patient assessment and care delivery, health professional and caregiver training, and real-world data collection will further augment the ability to move the field forward.

The Sidney Kimmel Cancer Center (SKCC) at Jefferson Health launched the Geriatric Oncology Center of Excellence (GOCE) in November 2022. The GOCE is an important differentiator with the mission of providing the infrastructure necessary to assess the complex and multilevel needs of older adults with cancer, develop tailored care plans that optimize health outcomes, and improve the QOL and survivorship for this unique patient population. It builds on 12 years of consultative experience within the Senior Adult Oncology Center (SAOC), the multidisciplinary outpatient GA clinical consult team, which has now been incorporated structurally into the GOCE. The GOCE will serve as a sought-after training hub to expand a geriatric-sensitive work force, and it will create a research powerhouse designed to improve outcomes, inform best practices, foster paradigm shifting breakthrough discoveries, and enhance representation for a patient population that is rapidly expanding. This center is composed of five cross-functional pillars including (1) Basic Science Research, (2) Translational Research, (3) Clinical Care Delivery and Survivorship (incorporating the SAOC), (4) Population Health Research, and (5) Training and Education (Fig 1).

Research done in the Basic Science pillar will address the aging and cancer interface including senescence, telomere shortening, immune exhaustion, the aging microenvironment, chronic inflammation, and clonal hematopoiesis as drivers of cancer development and growth in the aging population. This work is informed by input from the communities served by the cancer center and will serve as the basis for multi–principal investigator grant development and the development of novel paradigm shifting investigator-initiated trials specifically addressing questions relevant to older adults with cancer. The work in the Translational pillar will be guided by relevant questions developed in the Clinical Care Delivery and Population Health pillars and also informed by the seven-county catchment area served by the

FIG 1. Structure of Sidney Kimmel Cancer Center Geriatric Oncology Center of Excellence.

Sidney Kimmel Cancer Center in Southeastern Pennsylvania and Southern New Jersey. Research areas focused on older adults with cancer for the Population Health pillar include remote monitoring, health informatics, cardiology and aging, disparities, health equity, survivorship, and value-based care.

The Clinical Care Delivery pillar will continue to focus on the highest quality care delivery through the multidisciplinary clinic, using the G8 tool to screen all new older adults with cancer to assess who would benefit from a more in-depth GA. It will deploy novel strategies for expanding access across the larger health system using telehealth and exploring opportunities for nursing and patient-led assessments to ensure compliance with the ASCO guideline. As a certified Age-Friendly health system by the Institute for Healthcare Improvement (IHI), the center will expand Age-Friendly principles across the larger cancer center, bridging inpatient, outpatient, and transitions of care. Using this framework, the clinical pillar will provide geriatric oncology-sensitive survivorship, rehabilitation medicine, and cardio-oncology support and structure to develop relevant research questions.

An essential responsibility of the Center is to train the next-generation geriatric oncology-sensitive health care professionals, including physicians, nurses, pharmacists, navigators, social workers, nutritionists, and rehabilitation medicine providers. Expansion of current infrastructure will enable training of future geriatric oncologists and health care professionals to meet the increasing demand. Using innovative education models such as Project ECHO, the Center will educate an interprofessional and interinstitutional workforce in geriatric oncology principles. Given the advancements in health care and changes in payment structures, most cancer care is provided in the outpatient setting and relies on unpaid caregivers to help manage.[51] In efforts to address this often overlooked care gap, the GOCE intends to provide training and support for caregivers and advocates in the specific issues that older adults face when diagnosed with cancer. As part of these training and education efforts, expansion of the existing programs to focus on older adults with cancer, including cardio-oncology, rehabilitation medicine, survivorship, and transplant/cellular therapy is planned.

CONSIDERATIONS IN THE COMMUNITY SETTING: THE COACH EXPERIENCE

The program for Comprehensive Oncology & Aging Care at Hartford (COACH) was established with the primary aim of integrating geriatric care into the routine daily oncology practice of all older patients at Hartford HealthCare Cancer Institute (HHC CI). An initial pilot project was conducted with the goal of testing the feasibility of integrating a screening tool, the modified G8 (mG8), into the daily clinic flow.[52] The primary aim of the study failed as the completion rate did not reach the predefined threshold for success, but findings from this study emphasized internally the inadequacy of classical performance tools measures: Among 34 patients with a good performance status (Eastern Cooperative Oncology Group 0-1), only 21% (n = 10) were found to be fit by the mG8 score.

The initial phase of the implementation was used as an opportunity to refine the GA operation and identify a process that would be the least demanding on the daily office flow and replicable in other settings. Empirical observation conducted during that period established that a GA visit scheduled immediately before the patient's initial consultation is the most impactful on patient's oncological treatment plan and least burdensome to patients and their caregivers. In addition, it was determined that the GA process would be reproducible in other sites of the cancer institute only if the GA format was improved to be less operator dependent. The Epic Geriatric Oncology Assessment (Epic GOA), an electronic GA tool that is fully integrated into the electronic medical record system (Epic Systems), was developed on the basis of the electronic Rapid Fitness Assessment (eRFA).[37] The Epic GOA performs an automated assessment of a patient's frailty status on the basis of the total number of identified geriatric impairments, estimates chemotherapy toxicity risk using the Cancer and Aging Research group (CARG) tool,[53] and suggests geriatric interventions. On the basis of its user-friendly interface, the Epic GOA became the cornerstone of the geriatric oncology dissemination strategy throughout different sites of the Hartford HealthCare Cancer Institute as it allowed health care professionals of various backgrounds to perform the GA (Fig 2). In the future, the Epic GOA will be implemented at all sites of the HHC CI. As a result of the activity of the COACH team, the HHC CI was designated as age-friendly health care system by the Institute for Healthcare Improvement (IHI) Age-Friendly Healthcare system.

Similar considerations and approaches can be implemented in other community-based practices. Given that community-based practices often have fewer resources, selection of easy-to-use tools that are doable with minimal direct provider involvement is critical to the feasibility and successful implementation of any cancer and aging program. Integration of these data with one's electronic medical system can help facilitate data synthesis and transmission and integrate it into the clinic flow. Seamless integration of data can help alleviate some of the burden that clinicians may perceive with GA.

INTERNATIONAL PERSPECTIVES AND CONSIDERATIONS

Cancer and aging programs have been established in many countries and contexts outside of the United States as well.

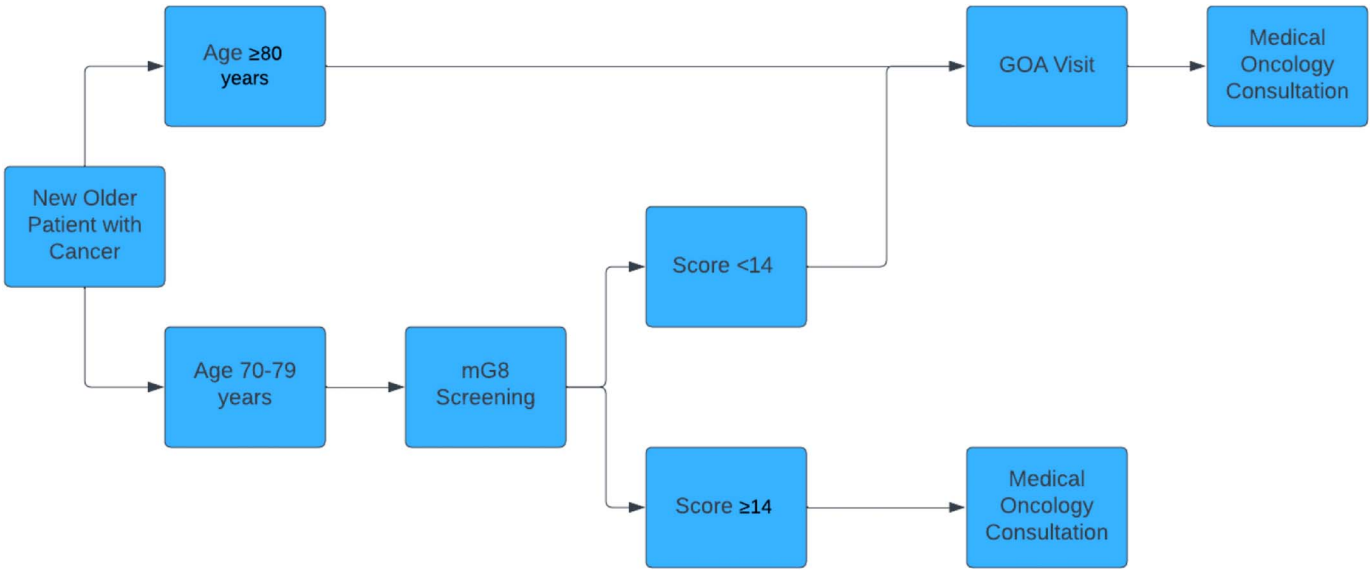

FIG 2. The COACH process. COACH, Comprehensive Oncology & Aging Care at Hartford HealthCare; GOA, Geriatric Oncology Assessment; mG8, modified G8.

Differences in health care systems, including structure and delivery of health care, role and availability of geriatricians, clinician compensation models, and the political and socioeconomic climate may present different opportunities and/or challenges than those faced in the United States.

Recognition and endorsement of geriatric oncology is variable. In some countries, the impact of the aging population on health care and cancer care in particular is well established, while in other countries this is just starting to be recognized. Education and training in geriatric oncology is also quite variable. Although the United States established fellowship training programs in geriatric oncology in the late 1990s,[54] in some countries, geriatric medicine is not even a recognized specialty.[55] Clearly, the challenges faced by countries in the latter category are very different than those with well-established training programs. In countries where geriatric medicine is not established, education about core principles of geriatrics, including the idea of physiological versus biologic age and the concepts of GA and syndromes, will need to be done to establish the foundations of any initiatives to improve care of older adults with cancer. Even in countries with established specialties of geriatrics and oncology, studies suggest that most health care professionals do not receive training in areas outside of their specialty, leading to gaps in knowledge and skills to ideally care for the aging cancer population.[56-59] The International Society of Geriatric Oncology (SIOG) has worked to increase education in geriatric oncology in certain regions such as Asia where exposure to geriatric oncology has thus far been limited.

The specific health care context, particularly the payer and the method in which clinicians are reimbursed, can be important. In countries such as Canada and Mexico, for example, where clinicians are paid a set salary and/or are paid per patient seen (fee for service) but in which the procedures performed (in this case the GA) are not a factor, funding of the clinician may be less of a barrier to the implementation of a cancer and aging program. However, for health care systems in which physicians are not reimbursed for doing a GA, exploration of alternate funding models and/or supplemental funding may be an important consideration.

SUSTAINABILITY

Beyond implementation, considerations on how to sustain a cancer and aging program are important. Sustainability includes strategies for ongoing access to resources and personnel, as well as ensuring longevity of the program as it expands.

Demonstrating the value of the program to clinicians and administrators is important. Value to clinicians includes ensuring a smooth and efficient referral process, timely access, good communication, and improvement in patient care. For some clinicians, this will mean receiving help with decision making or optimizing patients' functional status to enable them to receive treatment, while for others, this may mean managing geriatric syndromes, such as falls and dementia, that oncologists feel they do not have the capacity to manage. Building relationships with referring services and entrenching the program into the oncology culture are important to developing, sustaining, and growing a cancer and aging program. For geriatricians leading the development of a cancer and aging program, attendance at oncology rounds,

including multidisciplinary tumor boards (a staple of oncologic care), may be helpful to establish a presence and provide geriatric-related perspectives to the discussions.

Demonstrating value to administrators may include providing metrics showing improvements in outcomes for older patients (safety, quality, and decreased unnecessary admissions, emergency room visits, and ICU stays), patient retention, and cost savings. Understanding what outcomes administrators and leadership of the cancer center will want evaluated should be determined at the inception of the program to ensure these metrics are collected. For those who work in an academic institution, establishing a program of research with visible outputs, including research projects completed, grant funding, and publications, can bring prestige and recognition to the institution and thus engender ongoing support for the program. Similarly, establishment of the cancer and aging program as a beacon of excellence for care of older adults with cancer may attract philanthropic donations to the cancer center. This may also help to sustain the ongoing sustainability and growth of the program.

Beyond monetary considerations, as the program grows and continues, it is important to plan for growth and possible personnel changes by continuing to engage health care personnel interested in caring for older adults with cancer. Recruiting more physicians, nurse practitioners, physicians assistants, and health care professionals not only increases the capacity of the program but also ensures that the program is able to continue to function during absences or if the primary clinician leaves. One method of engaging new clinicians can be to establish a formal training program. This may be particularly important in regions where geriatric oncology is less well established and where training opportunities in the country are limited. Formal succession plans to ensure stability of the program should be put in place early and frequently updated.

CONCLUSION

There are now robust data supporting the use of GA to improve outcomes in older adults with cancer receiving systemic therapy and/or surgery. This has been endorsed by several international organizations including ASCO. Challenges to developing and implementing a cancer and aging program vary depending on the health care context. Making a case to stakeholders and building coalitions with those interested in and passionate about caring for older adults is a critical first step. Selection of an appropriate model and referral criteria that fits the local health care context is a key next step. Creating a business proposal that considers resources required and addresses the benefits of an aging and cancer program to the institution are important next steps to garner institutional support. Given the enormous potential impact of a cancer and aging program to improve outcomes of older adults with cancer and the adaptability of GA to multiple contexts and resource settings, health care providers and administrators should move beyond dwelling on barriers to implementing GA and work to address these challenges in order for older adults with cancer to have access to the highest-quality cancer care that matches their goals.

overview

Cancer is an increasing global public health burden. Lately, more emphasis has emerged on the importance of heredity in cancer, mostly driven by the introduction of germline genetic variants–directed therapeutics. It is true that 40% of cancer risk is attributed to modifiable environmental and lifestyle factors; still, 16% of cancers could be heritable, accounting for 2.9 of the 18.1 million cases diagnosed worldwide. At least two third of those will be diagnosed in countries with limited resources—low- and middle-income countries, especially where high rates of consanguine marriage and early age at diagnosis are already prevalent. Both are hallmarks of hereditary cancer. This creates a new opportunity for prevention, early detection, and recently therapeutic intervention. However, this opportunity is challenged by many obstacles along the path to addressing germline testing in patients with cancer in the clinic worldwide. Global collaboration and expertise exchange are important to bridge the knowledge gap and facilitate practical implementation. Adapting existing guidelines and prioritization according to local resources are essential to address the unique needs and overcome the unique barriers of each society.

INTRODUCTION

Cancer is an increasing global public health burden. Lately, more emphasis has emerged on the importance of heredity in cancer, mostly driven by the introduction of germline genetic variants–directed therapeutics. It is true that 40% of cancer risk is attributed to modifiable environmental and lifestyle factors[1]; still, 16% of cancers could be heritable,[2] accounting for 2.9 of the 18.1 million cases diagnosed worldwide.[3] At least two third of those will be diagnosed in countries with limited resources—low- and middle-income countries (LMICs), especially where high rates of consanguine marriage are already prevalent.[3] Early age at diagnosis is a hallmark of cancer in LMICs, which may reflect a higher rate of hereditary cancer compared with other parts of the world. For example, two third of breast cancer cases in LMICs are diagnosed before age 54 years compared with one third of BC cases in high-income countries (HICs), with a median age at presentation a decade younger than those in HICs.[4,5] Black patients with breast cancer in sub-Saharan Africa (SSA) are twice as likely than White patients in SSA to be the triple-negative subtype.[6] These molecular features are hallmarks of hereditary cancers; indeed, genetic testing for pathogenic sequence variants in the tumor suppressor genes *BRCA1* and *BRCA2* in a series of Nigerian patients with breast cancer suggested a rate of cancers in women with *BRCA1* or *BRCA2* germline-pathogenic sequence variants to be higher than White populations.[7] This creates a new opportunity for prevention, early detection, and recently therapeutic intervention. However, this opportunity is challenged by many obstacles along the path to addressing germline mutations in patients with cancer in the clinic worldwide (Table 1).

THE CHALLENGE OF REFERRAL

The era of clinical cancer genetics was ushered by the discovery of *BRCA1/2* in the mid-1990s. Since then, most HICs have multidisciplinary teams to manage genetic counseling and testing for high-risk and moderate-risk cancer susceptibility genes to guide risk-reduction recommendation and clinical management. However, even in HICs, there is disparity in access to cancer genetics services. For example, Black women were 40% less likely to undergo BRCA1/2 testing than White women in a population-based study in two US states.[8] Another report demonstrated that physician referral rates for women who met criteria for referral to genetic testing from the US National Comprehensive Cancer Network (NCCN) differed significantly by ethnic background; only 75.7% of Black non-Hispanic patients compared with 92.7% White non-Hispanic patients were actually referred.[9] Uptake of genetic counseling, once appropriately referred, was not significantly different by ethnic background. The racial disparity in referral to genetic testing could be explained by a variety of factors, such as inadequate physician education on the prevalence of hereditary risk in patients, physician association of genetic cancer

Author affiliations and support information (if applicable) appear at the end of this article.

PRACTICAL APPLICATIONS

- Awareness campaigns should target society, health workforce, and policymakers alike to raise awareness and education about the importance of germline testing and its implications, particularly in prevention and potentially targeted therapeutics, to facilitate and support widespread implementation.
- A culture-sensitive standardized approach for referral, consent, counseling, and testing needs to be adopted to streamline the process within the oncology service visit.
- Genetic misdiagnoses may occur if genomic tests are developed using only specific populations, and this misdiagnosis extends to both majority and minority populations.
- The universal shortage of genetic counselors mandates educating oncology professionals on the subject of cancer genetics.
- Overcoming the financial barrier, together with collaboration, is key to capacity building, accessibility, and sustainability of germline testing.

TABLE 1. Types of Challenges Related to Germline Testing Around the Globe, in All Resource Settings, With Suggested Possible Solutions

Type of Challenge	Possible Solutions
The challenge of referral	Develop standardized tools for assessing eligibility for testing
	Multidisciplinary team education
The challenge of indication	Focus on those at risk rather than expanding testing to everyone
The challenge of uptake	Culture-sensitive genetic counseling
	Streamline the process within oncology clinic visit
	Public policy to protect against genetic discrimination
	Awareness campaigns
The challenge of interpretation	Focus on those at risk rather than expanding testing to everyone
	Development and improvement of tools such as RNA sequencing and in silico analysis
	Promote collaboration across the world to facilitate sharing information from different populations
The challenge of genetic counseling	Support expanding programs to train more genetic counselors
	Multidisciplinary team education
	Utilization of telemedicine and artificial intelligence
The financial challenge to access	Collaboration between researchers and pharma
	Research to support cost efficacy in cancer care (prevention and treatment)
	Support from insurers and governments

pathogenic genetic variants with certain populations, for example, Ashkenazi Jewish, communication barriers on the basis of cultural norms, differences in patient awareness and assertiveness between different ethnic backgrounds or societies to discuss the issue of heredity, and finally implicit bias. Another ethical challenge for the physician when considering referral, especially in a therapeutic setting, will be the financial implications. For example, if patients with pancreatic cancer do not have access to poly (ADP)-ribose polymerase (PARP) inhibitors, it would be very hard to counsel them about germline testing, still relatively expensive in most LMICs, and discuss potential benefit for relatives, while informing them of a therapeutic choice they cannot afford and, therefore, cannot access.

Besides, the importance of physician education worldwide, developing standardized tools for assessing eligibility for testing, would be more practical to eliminate the effect of physician bias and streamline the referral process. The standard tool would facilitate the accommodation of new indications in this era of rapidly changing indications for genetic testing amid busy clinics.

THE CHALLENGE OF INDICATION

Guidelines detail which patients to refer to genetic testing; however, those are revised frequently and have become more complicated, adding to the burden of the busy physician to keep up and check for each patient. Lately, they have recognized additional genes, besides *BRCA1/2*, for which management guidelines have been proposed or are in development. Testing for multiple genes simultaneously makes panel testing a logical option rather than sequential single-gene testing. Panel testing addresses not only the genetic heterogeneity of hereditary cancer syndromes but also the phenotypic overlap among carriers of different mutated genes. For example, breast cancer is common among women with a germline *BRCA1/2* pathogenic genetic variant and in those with pathogenic genetic variants in *PALB2*, *TP53*, *ATM*, or *CHEK2*, among others.[10,11] Consequently, when requesting a germline genetic test, it is important to understand the different kinds of tools available and individualize the choice during precounseling. Sanger sequencing was the primary method used for DNA sequencing for several decades before being largely replaced by newer technologies, such as massive parallel sequencing. Sanger sequencing could be used when a genetic variant is known to do cascade testing in a family. It can also be used when a specific syndrome with specific variants is suspected, such as MEN1 syndrome or DICER1 syndrome.[12]

Massive parallel sequencing is a high-throughput method used to determine the nucleotide sequence or fragment of

an individual's genome. This approach uses DNA sequencing technologies capable of analyzing numerous DNA sequences simultaneously.[12] This technology is also referred to as next-generation sequencing. It is useful for studying a set of genes, often called a panel, that can range from 2 to 1,000 genes. Access to this technology is limited in LMICs, so testing is performed by sending abroad further complicating the process of testing and subsequently adding to the financial challenge. Massive parallel sequencing can also be used for coding exome sequencing and whole-genome sequencing. However, exome sequencing and genome sequencing are not typically indicated in clinical settings for patients with cancer and are only used in research settings. Multiplex ligation probe assay, polymerase chain reaction, or other method to detect structural variants, including copy number variants and genomic large rearrangements, should always be included.

Several founder mutations (in particular *BRCA1/2* mutations) occurring among defined ethnic groups or individuals from a specific geographic area have been observed. Their identification can facilitate diagnosis and make it cost-effective by focusing testing on those variants initially.[13] For example, deletion 9-12 of *BRCA1* represents 30% of all the cases of BRCA1/2 pathogenic variants in Mexican population.[13]

To complicate the issue of the appropriate indication further, some argue for expanded panel testing for all patients with cancer. Their argument is that many clinically actionable variants are missed by history- or syndrome-focused testing. Indeed, among 2,984 patients with cancer unselected for high-risk, germline testing detected germline variants in 13.3%, ≈50% of which would have been missed by testing guidelines.[14] A couple of studies reported a similar rate of pathogenic/likely pathogenic (P/LP) variants among patients with breast cancer or gynecologic malignancy who met and those who did not meet the NCCN testing criteria.[15,16] This translates to half the patients with a clinically actionable P/LP germline variant not meeting the NCCN testing criteria and missing the therapeutic opportunity. In response to the aforementioned findings, the American Society of Breast Surgeons in 2019 recommended panel testing to be offered to all individuals with a personal history of breast cancer and even recommended updated testing of those who had been previously tested.[16] However, reanalysis of the data reported in one of the studies above,[15] including only variants in genes with definitive evidence for breast cancer susceptibility,[17] determined that of patients who met the NCCN guidelines, 6.47% had a P/LP variant, whereas of those patients who did not meet the guidelines, 3.75% had a P/LP variant, translating to missing four P/LP variants in high-risk genes, three in *BRCA2*, and one in *PALB2*. This represents 0.4% of the tested population, with 54% of patients being found to have variants of unknown significance (VUSs). Most of the variants identified in patients who did not meet the NCCN guidelines were in the moderate-risk genes *ATM*, *BARD1*, and *CHEK2*, which do not affect surgical management. These findings are a testimony for the efficacy of guidelines to guide testing of those at high risk in the current era, while reducing the rate of detection of VUSs. Similarly, germline variants were identified in 15.7% of 515 patients with esophagogastric cancer, with 55.2% of those with high- and moderate-penetrance variants not identified by current testing guidelines; however, most were incidental or unrelated to the patient diagnosis.[18] These results call attention to the implications of expanded germline testing away from guideline indications. Besides the financial implications, the consequences to both the patient and the physician are not trivial. The patient will suffer from unnecessary anxiety because of the VUSs, whereas an incidental and unrelated germline P/LP genetic variant to a patient with advanced tumor will be quite challenging to address. It will be tough to explain that they are unrelated to the patient diagnosis while recommending cascade testing for family members for someone in desperate need for a promising result to improve outcome. The busy physician will be overwhelmed with results enriched for VUSs. Those will take time to interpret and explain to patients and may require follow-up, additional testing, or review in case of reclassification,[19] creating unnecessary burden for the physician. More importantly, it will also increase the chance of misinterpretation with subsequent inappropriate recommendations for the patients. A recent study reported that the confidence of surgeons in discussing testing increased with the volume of patients with breast cancer they treat.[20] Many surgeons (higher volume, 24%; lower volume, 50%) managed patients with *BRCA1/2* VUS the same as patients with *BRCA1/2* pathogenic genetic variant, and one half of average-risk patients with VUSs underwent bilateral mastectomy without discussion with a genetic counselor.[20] There is no short-term solution to the recognized shortage of genetic health counselors,[21] and oncologists will be faced with the need for continuous education to be able discuss germline testing finding and their implications. Therefore, physician awareness of those implications is important while focusing on minimizing the VUS rate by restricting testing to genes that are clinically relevant to the patient's diagnosis.[22]

One might consider polygenic risk scores (PRSs); however, those are subject to the same biases that affect virtually all clinical genomic information, including the limited ethnic diversity of the data used in their development.[23] Most cancer genomic studies have predominantly included populations from Western Europe or North America and, to a lesser extent, East Asia. Other populations, including those from southern Asia, South America, Africa, and Middle East, are remarkably under-represented in these studies, posing

important limitations to the generalizability of findings from one population to another, therefore limiting the interpretation of PRSs, leaving guideline-driven testing the most balanced strategy for now. Currently, NCCN recommends genetic testing for all individuals with ovarian, pancreatic, or advanced-stage prostate cancer, regardless of age at diagnosis, ethnicity, or family history. Indeed, it is estimated that less than a quarter of those eligible for genetic testing in the United States had such testing in 2015, leaving approximately 1 million individuals untested.[15] It seems more reasonable to focus on improving the genetic testing rate among those at risk, as defined by the guidelines, rather than expanding testing to all. A standardized tool to help the busy physicians, especially where genetic counselor is not available, would be a great asset to incorporate in the oncology clinic visit.

THE CHALLENGE OF UPTAKE

The obvious challenge of referral is more complicated by the attitude challenge, driven by social, cultural, and religious barriers to genetic testing. Some patients believe that genetic testing is not important if they do not have children or because of lack of perceived benefits; the latter would preclude discussion with family members as well. One study demonstrated that patients believed genetic testing was not important or beneficial because of insufficient information regarding the rationale for, and benefits of, genetic testing.[24] Patients can be overwhelmed with their diagnosis and miss appointments for genetic counseling. Therefore, the mainstreaming of genetic counseling and molecular testing during oncology outpatient consultations, whether by the oncologist or by the onsite genetic counselor, may lead to a decrease in attrition. When the process of genetic education, consent, and testing was accommodated during scheduled patient appointments (such as during chemotherapy), thus minimizing patients' travel and wait time, the number of patients lost to follow-up was reduced to 4%.[25] This is in contrast to a reported rate of 19.6% when patients were referred for genetic testing by the oncology service (in which genetic counselors were not present in the outpatient clinic).[26] Some patients do understand the importance of genetic testing, but they are worried to know that a genetic variant might be present with subsequent effect/stigma on future generations, such as children and grandchildren. Education about the potential for risk-reduction strategies could reassure them to pursue testing and inform relatives. Even among relatives receiving risk communication support and no-cost testing for familial variants, the rate of cascade testing uptake was only 17.6%,[14] consistent with reported estimates as low as 20%-30%.[27] The latter estimate is also partially driven by restrictions on direct communication between physicians and patients' relatives. The low rate of uptake of cascade testing, even among those diagnosed based on family history, limits the positive impact of germline genetic variants testing on prevention and early detection, challenging its clinical utility to support early detection at a societal level.

There is a real concern about genetic discrimination (GD) across cultures, especially high in the context of insurance, employment, and within social relationships. Some countries do have legislation prohibiting GD, but most do not, especially those with limited resources. A recent study outlined public policy approaches across the globe used to prevent GD. They identified regions featuring extensive policy-making activities (North America and Europe), followed by regions with moderate policy-making activities (Australia, Asia, and South America) and regions with minimal policy-making activities (the Middle East and Africa).[28] Those legislations, however, do not seem to (completely) alleviate fears of GD. Indeed, those legislations have limitations. For example, the Genetic Information Nondiscrimination Act in the United States covers employers in addition to health insurers but does not cover life or disability insurance.[29] In addition, there are ethnic differences in the perception of GD, mostly related to the possible use of genetic information when considering potential spouses for marriage and starting a family in Asia, but not North America and Europe.[30] In a Japanese public survey, the respondents were largely concerned about GD in the context of marriage and pregnancy (41.0%), employment (37.6%), and insurance (43.8%).[31]

Fear also seems to be fueled by previous experiences dealing with the social repercussions of living with an illness in the family. Interaction discrimination concerns seem to be very high, although subtle and implicit, often characterized by more spontaneous forms of stigmatization or disrespect, subsequently playing a pivotal role in the decision to undergo genetic testing.[32]

THE CHALLENGE OF INTERPRETATION

During variant interpretation, variants are classified into five tiers: pathogenic, likely pathogenic, uncertain significance (VUS), likely benign, and benign.[33] Pathogenic and likely pathogenic variants are considered positive results and are often referred to as mutations, although this term is no longer recommended by the American College of Medical Genetics and Genomics. Benign and likely benign variants are considered negative results. VUS are variants in which there is not enough information to classify them. Clinical decisions should not be based on these variants since 80%-90% of them are reclassified as benign or likely benign. VUS pose a challenge, particularly in underrepresented populations where the percentage of VUS is higher because of a lack of representation in large public databases. For example, the proportion of Hispanic people is just 2% of the Cancer Genome Atlas for the glioblastoma cohort.[34]

Adequate clinical interpretability of genetic information mandates characterization and curation of novel variants for pathogenicity and thus clinical actionability. Therefore, it is anticipated that the proportion of VUSs will be higher in understudied populations until careful characterization and curation of these variants can be made.

Data diversity is required for the success of these activities. Studies of genetics and genomics are not optimized if the data used to generate clinically applied tests do not include data from ethnically diverse populations. Optimal discovery and clinical translation of genomic information requires the inclusion of diverse populations. Manrai et al[35] have reported that genetic misdiagnoses may occur if genomic tests are developed using only White populations, and this misdiagnosis extends to both majority and minority populations. Teo et al[36] have demonstrated how multicenter (multiethnic) studies in African populations can yield novel insights about the underlying genetic architecture of human disease because of the unique nature of the African genome. Genomic studies based in African populations are more generalizable to other world populations compared with the same studies performed in non-African populations because of the features of African genomic architecture.[37,38] Population-specific variants, substantial differences in variant frequencies across populations, effect-size heterogeneity, locus heterogeneity (ie, differences in causal variants across populations), and haplotype diversity (linkage disequilibrium differences across populations) all contribute to the potential error in the use of genomics if only single (eg, European descent) populations are studied.[39,40] Friebel et al[41] have recently reported the existence of pathogenic genetic variants seen in African Americans who are of likely African origin. Thus, identification of variants globally can inform genetic medicine in other (eg, non-African) populations. Finally, design and sample size considerations for genomic research studies are highly dependent on accurate knowledge of allele and genotype frequencies.[42] Thus, a lack of diversity in genomic research can limit discovery and translation of genomic information so that all can benefit.

THE CHALLENGE OF COUNSELING

Genetic counselors are professionals with specialized education in genetics (and recently genomics) combined with counseling skills.[43] They assess an individual's risk of a genetic disorder, prepare them for genetic testing, get consent, communicate the results and help in the management of the patients' genetic variant, and provide support to follow with cascade testing for their relatives. The challenge starts when faced by the financial burden of both germline testing and its subsequent implications in terms of prevention and therapy. Despite the significant drop in the prices of panel germline testing, those prices are still unaffordable in most LMICs. A recent study estimated the cost of panel testing to be well above the annual per capita income of LMICs—$1,500 in US dollars (USD) to $6040 USD,[44] let alone the cost of interventions needed for prevention, early detection, or treatment, particularly medications such as PARP inhibitors.

Consenting patients is a complex issue. It should cover the types of results that may come back from the laboratory (ie, pathogenic, uncertain, or benign) and the meaning of each in terms of future risk and disease management, their implications, for both the individual patient and also their relatives, and further plans for genomic data handling. Not only does it address the educational component of counseling but also the psychosocial aspect to support the patient throughout the testing process. However, with mainstreaming of germline testing and universal shortage of genetic counselors, clinicians are taking over the role of genetic counseling and testing. This approach proved effective in a study where patients with prostate cancer were counseled by their urologist or medical oncologist—as part of their routine clinical care and for enrollment in the Germline Genetics in Prostate Cancer Study.[45] Most patients (98%) reported being satisfied with the overall quality of pretest counseling, and 74% of patients elected to undergo genetic testing. Therefore, oncologist training can expand access to germline testing, but post-test counseling is still a challenge best met by professional counselor. Similarly, some researchers started an internet algorithm (chatbot) to guide patients through their testing journey.[46] While those can provide information about tests and their potential results, they cannot replace the psychosocial support that focuses on the needs of patients to understand, adjust, and incorporate this new information into their lives. The psychosocial support is augmented by cultural competence of the genetic counselor. Genetic counselors need to understand the social and cultural influences on patients' health decisions and behaviors, especially those from minority groups. This cultural competence is important to properly support the autonomy of the individual while assisting them in making their own informed choices.[47] Since the individual's decision is not only driven by medical information but also personal, social, and even religious background, cultural competence of genetic counselors is key to increase utilization of genetic testing and counseling.[48] Another challenge for genetic counselors from the majority ethnic group is counseling individuals from the minority group in a multiethnic society.

The quantitative challenge is a universal challenge, with best estimates of only 12 per million population in the United States and 5 per million population in the United Kingdom compared with 20-fold less, with 40 genetic counselors in the Arab region (0.1 per million population).[49] Some countries are now establishing training programs in genetic counseling. However, such programs need to grow significantly to train enough local talent and to meet the significant genetic counseling demand.

THE SURGEON PERSPECTIVE

From the surgeon's point of view, germline molecular testing plays a foremost role in guiding the extent and indication of surgery in patients with known germline genetic variant. For example, even patients with early-stage colon cancers and Lynch syndrome can be offered a total colectomy as opposed to a segmental resection because of the high risk of metachronicity. In many practices, this is guideline-driven, like the NCCN in the United States[50] and National Institute for Health and Care Excellence in the United Kingdom,[51] and these guidelines address the different aspects of the process that are relevant for that health care system. However, in LMICs, many aspects of those guidelines might not be applicable or even affordable.[52] The lack of local guidelines jeopardizes patients' rights and access.[53] In addition, as detailed above, data on the risks for the different genetic variants especially in the cancer setting and the models we use to assess the risks are based mainly on North American and European population. There is not enough knowledge about the genetic risk in LMICs when it comes to the pathogenicity of genetic variants or their level of penetrance. Those uncertainties in assessing the risk, and the lack of expertise in communicating the risk and the benefit of the risk-reducing procedures, make informed consent become an issue.[54]

Decisions regarding the extent of surgery and surveillance are especially complicated—not only are they dependent on the mutational landscape but also on the patient- and system-related factors. The discussion is affected by patient age, education, family, culture, society, and sometimes religious beliefs.[53] For example, risk-reducing mastectomies in many societies are still seen as a taboo.[55] Even when at-risk individuals opt for surgery, availability and cost of breast reconstruction locally is another challenge. The surgical expertise and reconstruction availability are very variable in LMICs, in addition to variations in different parts, and even between the private and public sectors, creating further health care disparities that are multifactorial and complex.[55]

CONCLUSION

The WHO cautions that while genomics can contribute to improving global health equity, equity can only be achieved if the genomic health divide is kept in check and ultimately bridged through equitable economic investment, clinical research, and provision and use of genomic services and technologies globally.[56] Therefore, acknowledging and supporting the importance of collaboration and exchange of information and expertise between HIC and LMIC researchers bridge the knowledge gap and facilitate implementation. Similarly, ASCO—in a policy statement—addressed the importance of optimal deployment of new technologies in cancer genetics in clinical practice.[57] ASCO recommended quality assurance in genetic testing, education of oncology professionals, and access to clinical cancer genetic service. While those facilities are growing in HICs, they are still in their infancy in LMICs. Adaptations of existing guidelines are needed to address the local needs of each society while prioritization is done according to available resources while building sustainable capacity.[58,59] Meanwhile, awareness and education campaigns can help overcome the challenges discussed above. They should focus not only on patients and societies but also on policymakers.

Colorectal Cancer Screening in the Middle East: What, Why, Who, When, and How?

Ali Shamseddine, MD[1]; Laudy Chehade, MD[1]; Layal Al Mahmasani, MD[1]; and Maya Charafeddine, MPH[1]

overview

The incidence of colorectal cancer (CRC) in the Middle East is increasing, especially among those younger than 50 years. Risk factors including obesity, sedentary lifestyle, and dietary changes are associated with the epidemiologic shift and are a result of socioeconomic changes happening in the region. Worldwide, CRC screening is associated with decreased incidence and mortality of CRC, but screening uptake is still low in the Middle East because of cultural barriers and lack of awareness; in addition, most countries do not have national screening programs. Knowledge of CRC screening and participation rates vary among different countries, but overall they are low. Both primary and secondary prevention approaches are needed in the Middle East, and cost-effectiveness is important in choosing screening modalities. Although colonoscopy is considered the most robust screening method, stool-based testing may be an acceptable screening strategy in resource-limited settings, and focusing on high-risk individuals such as those with hereditary CRC might be the most cost-effective strategy. In addition to financial limitations in many countries in the Middle East, human displacement places an extra toll on cancer control strategies in the region.

INTRODUCTION

The Middle East extends between the southern and eastern borders of the Mediterranean Sea and includes the Arabian Peninsula, Iran, and Afghanistan. Despite sharing some common cultural characteristics, the population in the Middle East is ethnically heterogeneous, and countries have diverse economies and demographic constitutions. The population in this region is the youngest in the world second to sub-Saharan Africa, with only 5.31% of the population being older than 65 years.[1] The median age distribution varies widely among its countries; for instance, Kuwait and Cyprus have the highest median age of 37 years, whereas Afghanistan has the lowest (18 years).[2] However, life expectancy is increasing in most countries in the Middle East from around 60 years in 1980 to over 70 years. As a consequence, a surge in the geriatric population is anticipated in around 40 years. For instance, the elderly population is expected to double in Lebanon by 2050 and to increase by at least fivefold in Qatar, Kuwait, and the United Arab Emirates (UAE).[3] This increase in life expectancy is associated with a rise in the lifetime cumulative risk of cancer.[3]

Furthermore, countries in the Middle East have different financial capacities, and they vary in terms of the Human Development Index (HDI) classification.[4] This is tightly related to the availability of medical services and public health policies, which are not homogeneous across the region. With several countries undergoing economic transformations that drive lifestyle changes, the burden of noncommunicable diseases has increased in the Middle East, including that of colorectal cancer (CRC).[5,6]

CRC is the third most common cancer in the world, with 1.9 million new cases and 930,000 deaths in 2020. The incidence and mortality of this disease are expected to increase in the future to reach 3.2 million and 1.6 million, respectively, in 2040.[7] This global rise in the CRC burden also affects the Middle East, where limited knowledge about the disease and its prevention makes CRC screening an unmet need. In this article, we will review the epidemiological data of CRC in the Middle East and the available screening strategies while highlighting the challenges in screening adherence and special needs for the region.

WHAT IS THE STATUS OF CRC IN THE MIDDLE EAST?

The Middle East is a relatively lower-risk area for CRC. The age-standardized rates (ASR) for incidence and mortality in the Eastern Mediterranean region (EMR) are 9 and 5.1 per 100,000, respectively, compared with an incidence of 28.8 and mortality of 12 per 100,000 in Europe.[8] A higher incidence is seen in the western region of the Middle East, like countries in the EMR, compared with eastern and southern regions. However, the area has recently witnessed a rise in CRC incidence.[5] In addition, cancer mortality is on the rise in the region, as data from the International Agency for Research on Cancer have shown that between 2020 and 2040, the EMR will have the highest percentage

PRACTICAL APPLICATIONS

- Modulating modifiable risk factors is important for the primary prevention of colorectal cancer (CRC), and further research is needed to investigate the impact of lifestyle interventions on CRC incidence and mortality in the region.
- Addressing the knowledge gap regarding CRC prevention is needed in this region to encourage participation in screening.
- Cost-effectiveness is a main determinant of future CRC screening strategies in the Middle East, and governments should establish screening policies tailored to their resources.
- CRC screening targeting high-risk individuals may be a more suitable approach in low-income settings, as opposed to population-based screening. Stool-based testing is an acceptable screening tool, but measures should be taken to ensure the completion of follow-up colonoscopies for individuals with positive tests.
- Human displacement adds to the complexity of the situation and increases the cancer burden in host countries. Thus, providing screening access to refugees should be factored into national prevention plans.

increase in all cancer deaths, compared with other areas in the world (96.9% *v* 95.7% in Africa, 65.7% in South-East Asia, 64.6% in Western Pacific, 64.2% in the United States, and 34.4% in Europe), and the second highest increase in colon cancer deaths.[9]

The mean age at CRC diagnosis is 10 years younger in the Middle East compared with the United States (median age 60 *v* 71 years).[5,10] In addition, the incidence of early-onset CRC (age at diagnosis younger than 50 years) is increasing worldwide and in the Middle East. Furthermore, around 20% of all early-onset CRC cases worldwide are found in Asia.[11] The ASRs for CRC incidence before age 50 years in countries such as Jordan (6.6 per 100,000), Palestine (6.2 per 100,000), Libya (6.1 per 100,000), Oman (5.9 per 100,000), Turkey (5.9 per 100,000), Saudi Arabia (5.6 per 100,000), Cyprus (5.2 per 100,000), and Syria (5 per 100,000) are among the highest in the world.[8] In Iraq, a registry-based study showed an increased proportion of CRC in patients age 20-50 years from 1.46 per 100,000 in 2000 to 4.36 per 100,000 in 2019.[12]

The incidence of CRC is four times higher in countries with high HDI compared with those with low HDI, and by 2040, almost 80% of new CRC cases are predicted to occur in countries with high or very high HDI.[7,13] A similar pattern is found in the Middle East, where CRC is among the three most frequent cancers in the countries with high and very high HDI, as opposed to those with a medium and low HDI.[4,8]

The rising incidence, especially among the younger age groups, is mainly attributed to dietary and lifestyle changes, which include the Westernization of diet, increased intake of animal-source food, increased intake of red and processed meat, excess body weight, sedentary lifestyle, increased alcohol consumption, and smoking. These changes are related to the ongoing socioeconomic development in several Middle Eastern countries.[14]

The role of modifiable risk factors in predisposing to CRC was emphasized in a recent prospective European study that compared smoking status, alcohol consumption, BMI, and physical activity of a population at two time points 5.7 years apart. A combined score, the healthy lifestyle index (HLI), was calculated based on these factors (the higher the score is, the more the score is favorable). The results show that each 1 unit increase from baseline in the HLI was associated with a 3% decrease in CRC risk. In addition, patients with a favorable baseline score who had a deterioration in their lifestyle at follow-up (drop in HLI) had a higher risk of CRC compared with those who maintained their score (hazard ratio, 1.34; 95% CI, 1.02 to 1.75).[15] Studies from the EMR (including our group) used the population attributable fraction (PAF) to estimate the percentage of cancer that is due to the exposure to risk factors. Among 22 countries in the EMR, smoking, alcohol, and red meat consumption all contributed to the risk of CRC development in variable proportions, but the highest PAF was for high BMI (13.7% in men and 9.8% in women) and insufficient physical activity (6.2% in men and 8.7% in women).[16] Our published data on PAF for the Lebanese population showed that BMI >25 kg/m^2 is expected to result in 41% of CRC cases in male patients and 9% in female patients, low physical activity is expected to cause 17% of cases in male patients and 10% in female patients, and the contribution of low adherence to Mediterranean diet is 2% in both sexes.[17]

Another considerable risk factor is childhood obesity, which is associated with increased risk of cancer in adulthood and increased risk of death from colon cancer.[18,19] The prevalence of overweight children in the Middle East and North Africa (MENA) region is around 22.2%, and that of childhood obesity is 27.9%, which is the highest in countries such as Kuwait, Qatar, and Saudi Arabia.[20,21] Therefore, childhood obesity is a growing concern in the Middle East and can have serious ramifications on future cancer risk in the region.

With respect to genetic factors, it is estimated that the percentage of hereditary or familial CRC is similar to the

West, which is 10%-15%.[22] Studies from the Middle East have shown that 1% of all CRC cases in Saudi Arabia are due to Lynch syndrome,[23] and 7%-14% of cases in Egypt showed evidence for familial or hereditary CRC.[24] However, national registries and larger studies are needed to identify the burden of hereditary CRC and individualize screening in this population.

Inflammatory bowel disease (IBD), which encompasses ulcerative colitis (UC) and Crohn's disease (CD), is also a significant predisposing factor for the development of CRC, especially with UC. The cumulative increased risk of CRC in patients with UC at age 30 years is 18% higher than that in the general population.[25] The incidence of IBD is increasing in the Middle East, and a systematic review estimated that the incidence of UC and CD in the Arab world is 2.33 and 1.46 per 100,000 persons per year, respectively.[26] However, the data on the contribution of IBD to the burden of CRC in the Middle East are insufficient, and further research on the topic is warranted.

WHY IS CRC SCREENING UNDERUTILIZED IN THE MIDDLE EAST?

The benefits of CRC screening are well established in the literature, and studies in high-income countries have demonstrated around 30% decrease in the incidence rate and mortality of CRC because of the widespread uptake of screening.[27,28] For example, the mortality rates from CRC have dropped in the United States by 55% among male patients (since 1980) and 61% among female patients (since 1969).[27] Despite the proved benefits of screening, it is still underutilized in the Middle East. To start with, the knowledge and general awareness of CRC screening remains low. Studies from the UAE, Oman, Lebanon, Turkey, Iran, and Saudi Arabia demonstrated that between 6.5% and 38% of the surveyed individuals were aware of CRC screening, with the exception of one study in Lebanon where the rate was 55%, but this study was conducted at a tertiary care center and is not adequately representative of the whole population.[29-33] In the Middle East, national screening programs are generally lacking. Israel and Qatar have organized population-based fecal immunochemical test (FIT) screening since 1990 and 2016, respectively, with a target population between age 50 and 74 years.[34,35] Some countries, such as Jordan and the UAE, are adopting an opportunistic screening approach.[35]

With respect to screening uptake, the percentages vary across studies and countries, with participation rates as low as 7.5% in one study in Lebanon,[31] 8.3% in a study on high-risk population in Iran,[36] and 4% in another study from the same country.[37] On the other hand, participation rates are higher in Israel, reaching 64.7%, and among first-degree relative of patients with CRC in Turkey and Iran, reaching 48.7% and 49.2%, respectively (Table 1).[38-40] These variable results could be due to the diverse facilitators and barriers affecting access to screening, in addition to selection of participants and their perceived risk of CRC. Studies were conducted in several Middle Eastern countries to identify the barriers to screening. A systematic review from Iran showed that cost, shame, fear of cancer diagnosis, and lack of testing recommendation by the physician were the most common barriers to screening.[41] A national cross-sectional study conducted in Palestine showed that the lack of knowledge regarding screening, distrust in Western medicine, and embarrassments were independently associated with refusing screening on multivariate analysis. Additionally, some factors were identified as barriers to colonoscopy and not stool-based screening, such as education below secondary school, religious objection, and beliefs.[42] In Qatar, the most frequent perceived barriers to screening were the lack of symptoms or family history, low risk due to healthy lifestyle, and lack of reminders by health care workers.[43]

Overcoming these barriers, facilitating access to screening, and addressing misinformation regarding CRC risk and prevention are imperative to improve adherence to screening. Such public health strategies have proven to be effective in the past when applied to breast cancer screening. As an example, yearly awareness campaigns and subsidization of mammography in Lebanon since 2002 have led to almost 50% breast cancer screening rate uptake.[31] This was also demonstrated in a quasiexperimental study in Iran that used a questionnaire on the constructs of the Health Belief Model to measure the rate of participation in fecal occult blood test (FOBT) screening in average-risk men. Participants in the experimental and control arms were asked to answer the questionnaire at baseline, and then, those in the experimental arm received educational sessions on CRC screening. After 3 months, all participants were asked again to fill the questionnaire and were invited for screening. Initially, before intervention, there were no significant differences between the mean scores of both groups with respect to awareness, perceived susceptibility, severity, benefits, barriers, self-efficacy, social support, and cues to action. After intervention, the difference between the two groups was significant, and 74% of the participants in the experimental group underwent screening with FOBT compared with only 6% in the control group.[44]

WHO AND WHEN TO SCREEN?

Both primary and secondary prevention approaches are needed to curb the rising incidence of CRC in the Middle East. Primary prevention should target the modifiable risk factors that are strongly associated with the risk of CRC to promote high fiber diet, weight control, smoking cessation, and physical activity. Secondary prevention poses a more significant challenge because screening strategies derived from high-income countries cannot be blindly adopted in this region because of cultural differences and financial disparities. Even among Middle Eastern countries, not all

TABLE 1. CRC Screening Uptake in the Middle East

Country	Study	Population	Percent Participated in Screening	Screening Modality
UAE	[57]	Average risk	23%	FIT/gFOBT
Iran	[39]	FDR of patients with CRC	49.2%	Colonoscopy
	[67]	Average risk	42%	FIT
	[36]	High risk	8.3%	FOBT
	[37]	Average risk	4%	FIT
	[44]	Average risk	6% in the control arm; 74% in the experimental arm (received education)	FOBT
Saudi Arabia	[68]	Average risk	15.24%	Colonoscopy, stool test
	[69]	Older than 60 years	5.64%	FOBT, colonoscopy
Jordan	[70]	FDR of patients with CRC	62.1%	Colonoscopy
Lebanon	[71]	Average risk	15%	FOBT, colonoscopy,
	[31]	Average risk	7.5%	—
	[72]	Average risk	14.1% in the online survey; 6.1% in the in-person survey	Colonoscopy; FIT
Turkey	[73]	Average risk	12%	FOBT
	[74]	Average risk	7% outside of the study 89% screening part of the study	FOBT
	[38]	FDR of patients with CRC	48.7%	Colonoscopy
	[75]	Average risk	17%	FOBT, colonoscopy, sigmoidoscopy
	[76]	Average risk	30%	FOBT, colonoscopy, sigmoidoscopy
	[77]	FDR of patients with CRC	9% in parents and 20% in siblings	Colonoscopy
Palestine	[42]	Average risk	14%	Stool testing or colonoscopy
Israel	[40]	Average risk	64.7%	FOBT and colonoscopy
Oman	[30]	Average risk	6.1%	FOBT, colonoscopy, sigmoidoscopy

Abbreviations: CRC, colorectal cancer; FDR, first-degree relative; FIT, fecal immunochemical test; FOBT, fecal occult blood test; gFOBT, guaiac fecal occult blood test; UAE, the United Arab Emirates.

governments have adequate financial abilities to build and sustain a cancer control program.

In general, screening can be population-based, meaning that it is planned and implemented for the whole target population. This approach requires a robust public health scheme and health care infrastructure to ensure effective delivery, follow-up, quality assurance, and maximizing the benefits in a cost-effective manner. Screening can be opportunistic when asymptomatic individuals actively seek screening or are offered screening by a health care provider. This is opposed to organized screening when the target population is systematically invited for screening. The second approach consists of targeted screening for high-risk individuals (subpopulation) on the basis of factors related to their genetics or exposures.[45] Given the resource limitations, targeting high-risk populations with a family history of CRC can be a more feasible approach compared with mass screening.[14] The Hereditary CRC Network in the Middle East and Eastern Mediterranean countries suggests screening individuals with hereditary CRC (particularly Lynch syndrome) to be the most cost-effective strategy.[22]

In addition, a prediction model for CRC might be useful to stratify individuals who are otherwise deemed as average risk on the basis of the current guidelines and guide the choice of screening method and frequency accordingly.[46] By offering more intensive screening for high-risk individuals and less intensive testing for those at low risk, the risk-based screening allows a better allocation of resources, especially endoscopy services.[47] This can also facilitate the discussion with the individuals regarding screening and gives them a better understanding of their personal risk, which in turn can empower informed decision making and favor adherence to the screening recommendations.[47,48] For example, most guidelines use an age-stratified approach to identify the target population for screening, and this might inadvertently exclude younger patients who have a higher risk due to other factors such as sex, obesity, and smoking.[47] This is a pertinent issue for the Middle East,

where the early-onset CRC is on the rise. In a retrospective study in Northeastern Iran, the mean age at diagnosis of early-onset CRC was 40 years, and 57% of the early-onset CRC cases occurred between age 40 and 50 years.[11] Although the age to start CRC screening was lowered from 50 to 45 years, considering that the age of onset of CRC is younger in the Middle East compared with the West and that several countries have a high percentage of early-onset CRC cases, further reduction of the age for screening may be necessary. For instance, the Emirate of Abu Dhabi recommends screening with yearly FIT or colonoscopy every 10 years starting at age 40 years for the general population.[49] However, additional epidemiological data from the Middle East are needed in addition to cost-effectiveness studies to decide the age of screening.

HOW TO SCREEN?

CRC screening guidelines have been put in place by several major societies, and ASCO proposes resource-stratified guidelines, which recommend different screening methods depending on their availability. These include FOBT, FIT, colonoscopy, flexible sigmoidoscopy, computed tomography (CT) colonography, and FIT DNA testing.[50] Stool-based screening offers less discomfort to patients, is easier to administer, is less invasive, and is cheaper compared with other modalities. A retrospective study in Lebanon showed that the positive predictive value (PPV) of the FIT test for adenoma and/or carcinoma was 29.3%.[51] A pilot study in Iran on the feasibility of using FIT for screening demonstrated a PPV of 16.7% for any colonic neoplasm.[39] The numbers reported in these studies are on the lower range compared with the literature because of the relative lower prevalence of CRC in Lebanon and the age of younger participants and the lower rate of colonoscopy in the study conducted in Iran. Despite this, stool-based testing may be an acceptable population screening strategy in a resource-limited setting, given data from the literature supporting its diagnostic yield compared with endoscopy. A study from the Netherlands compared FIT testing (once every 2 years for four rounds in total) with once-only sigmoidoscopy or colonoscopy and found similar CRC detection rates in the as-screened analysis between the three modalities (0.8%, 0.5%, and 0.6%, respectively).[52] The NordICC trial evaluated the effect of population-based colonoscopy screening on CRC risk and mortality in individuals who were invited to get screened compared with the usual care group. At 10-year follow-up, there was an 18% risk reduction of CRC in intention-to-treat analysis and 30% in per-protocol analysis. The number of patients needed to invite for screening to prevent one case of CRC within 10 years was 455.[53] However, ensuring access to colonoscopy and an adequate quality of the procedure are necessary to maximize its efficacy for detecting lesions, which is not always attained in limited resource settings.

In a systematic review of 12 randomized controlled studies, Jodal et al showed that compared with no screening, sigmoidoscopy reduces CRC incidence (relative risk [RR], 0.76; 95% CI, 0.70 to 0.83) and mortality (RR, 0.74; 95% CI, 0.69 to 0.80). Sigmoidoscopy compared with biennial FOBT slightly reduced CRC incidence (RR, 0.80; 95% CI, 0.71 to 0.91) and mortality (RR, 0.85; 95% CI, 0.77 to 0.93). Sigmoidoscopy compared with annual guaiac fecal occult blood test (gFOBT) screening had little or no difference on incidence and mortality (RR, 1.07; 95% CI, 0.85 to 1.34). Therefore, sigmoidoscopy and annual and biennial gFOBT can reduce CRC mortality.[54] In another traditional and network meta-analysis, colonoscopy was found to be 50% more effective than gFOBT in reducing CRC mortality. The analysis favored colonoscopy over sigmoidoscopy (RR, 0.71; 95% CI, 0.45 to 1.11) and the latter over gFOBT (RR, 0.74; 95% CI, 0.50 to 1.09) in reducing CRC mortality, but these differences are not statistically significant. The study concluded that all three modalities are effective in reducing CRC mortality.[55] However, limited financial resources may restrict access to colonoscopy, especially that this invasive procedure required a certain level of expertise and availability of health care services. A follow-up colonoscopy for individuals with a positive stool test is important to ensure the success of the stool-based screening strategy. Countries such as Israel (71% follow-up rate)[40] and Iran (60% follow-up rate)[39] have better compliance compared with the United States where a recent study showed the follow-up rate of 56.1% after almost a year from the stool-based test.[56] By contrast, a study from the UAE showed a 30.5% rate of colonoscopy in individuals with a positive gFOBT/FIT.[57] These findings should be interpreted with caution as follow-up rates in clinical studies tend to be higher than real-life scenarios. However, this highlights the necessity of adequate follow-up and awareness to ensure the completion of colonoscopy in the case of a positive stool test.

Cost-effectiveness is another crucial aspect for selecting the appropriate screening tool. A study in Saudi Arabia compared between no screening, annual FIT, biennial FIT, once-only colonoscopy, and colonoscopy every 10 years for effectiveness and used resources. The results showed that the biennial FIT test between age 55 and 65 years is the cheapest efficient screening method. This could prevent three CRC cases and three deaths among– 1,000 individuals age 45 years, with an incremental cost-effectiveness ratio (ICER) of $8,800 per quality-adjusted life year. Once-only colonoscopy starting at age 55 years was similarly cost-effective with slightly higher costs (ICER of $8,900).[58] A study in Iran compared several screening modalities and found that CT colonography was the most effective yet the most expensive technique (2.58 billion Rials, which is around $60,000 as cost per cancer detected in 20 years of screening). Instead, flexible sigmoidoscopy was the most cost-effective method for screening the population

between age 45 and 65 years.[59] In Israel, a cost-effectiveness study found that colonoscopy every 10 years starting at age 50 years resulted in best reduction in mortality rate (93.7%) compared with no screening. On the other hand, the most cost-effective strategies were colonoscopy once or FOBT plus sigmoidoscopy, which yielded a reduction in mortality rate of 59.5% and 83.8%, respectively.[60]

SPECIAL CHALLENGES TO CANCER CARE AND PREVENTION IN THE MIDDLE EAST

Although some Middle Eastern countries are classified as high-income countries, most are low- to middle-income countries, and many face financial and/or political instability. As a result, services that aim at cancer prevention including screening tests face heightened risks of cutbacks, as governments work on reducing financial deficits and prioritize other essentials such as creating jobs.[61] Several studies have reported the impact of financial disparities and economic recession on primary cancer prevention worldwide and in countries such as Switzerland and Korea.[62,63] In Korea, which was affected by the global recession in 2008-2009, individuals were less likely to use costly screening modalities such as sigmoidoscopy or colonoscopy during the recession, regardless of their income. In addition, individuals with a lower income were less likely to participate in opportunistic screening.[62] Therefore, governments should put forth a plan for subsidization of screening, especially for individuals with low income, to boost the participation rate. A second challenge is the deficit in cancer awareness, which is present even in high-income countries, as detailed in Why Is CRC Screening Underutilized in the Middle East? Education level, health literacy, and employment status are all patient-meditated barriers to seeking care for cancer which influence knowledge and awareness of cancer symptoms.[64] A third and substantial challenge in the region is human displacement due to conflicts, violence, disasters, and climate change. The growing number of refugees resulted in increased health burden on host countries, many of which with strained economies, including chronic noncommunicable diseases such as cancer.[64] For example, a study showed that total cancer care for Syrian refugees in Turkey, Lebanon, and Jordan in 2017 is estimated to be around 33.68 million Euros, which is a considerable financial burden on these host countries.[65] This also reinforces the need for implementing cost-effective screening guidelines not only for citizens but also for refugees. Another aspect of military conflict is the prolonged exposure to carcinogens from warfare. For example, oil pollution in Lebanon and Kuwait, chemical contamination in Iraq and Sudan, and depleted uranium in Iran and Afghanistan are all concerning for dumping carcinogens in the environment and promoting the development of cancer, among other diseases.[66]

CONCLUSION AND FUTURE DIRECTIONS

The Middle East is experiencing an increase in the incidence of CRC, especially among young age groups, possibly because of socioeconomic development, dietary changes, and sedentary lifestyle. Despite this, existing CRC screening services are underutilized in the region, knowledge regarding CRC risk and prevention remains suboptimal, and national screening programs are lacking in most countries. Raising awareness, addressing cultural barriers, and providing accessible health care services are essential steps to increase adherence with CRC screening in the Middle East. Given the limited financial resources in many Middle Eastern countries and the added burden of human displacement and refugees, cost-effectiveness is a main determinant of the future CRC screening approaches.

Future directions should focus on identifying the factors driving the rise in CRC in the region to tailor more effective preventive strategies accordingly. In addition, comprehensive studies are needed to investigate the genetic components and environmental exposures influencing CRC occurrence in the region, as well as long-term follow-up studies on the effect of risk factor modulation and screening on CRC mortality. Finally, international collaborations within the Middle East can help in identifying common trends and determining best practices for CRC prevention in the region.

Managing Adverse Effects Associated With Poly (ADP-ribose) Polymerase Inhibitors in Ovarian Cancer: A Synthesis of Clinical Trial and Real-World Data

Michael Friedlander, PhD, FRACP[1,2]; Yeh Chen Lee, MPhil, FRACP[1,2,3]; and William P. Tew, MD[4]

overview

The use of poly (ADP-ribose) polymerase (PARP) inhibitor therapy is standard care in the management of patients with various malignancies including ovarian, breast, prostate, and pancreatic cancers. PARP inhibitors have been approved in different settings for patients with specific hereditary pathogenic variants, most notably homologous recombination repair pathways such as *BRCA1* and *BRCA2* genes. The vast experience with PARP inhibitors (olaparib, niraparib, rucaparib) has been in the management of epithelial ovarian cancer. There have not been any head-to-head comparisons of PARP inhibitors in randomized trials, and we can only perform cross-comparison on the basis of the reported literature. The three approved PARP inhibitors share several common adverse effects because of a class effect including nausea, fatigue, and anemia, but there are notable differences likely because of variations in their poly-pharmacology and off-target effects. Finally, patients included in clinical trials are often younger with a good performance status and less comorbidities than the real-world population, and hence, the potential benefits and adverse effects may not be superimposable. In this review, we describe these differences and discuss strategies to mitigate and manage adverse side effects effectively.

POLY (ADP-RIBOSE) POLYMERASE INHIBITORS: OVERVIEW

The use of poly (ADP-ribose) polymerase (PARP) inhibitor therapy is standard care in the management of patients with various malignancies including ovarian, breast, prostate, and pancreatic cancers. PARP inhibitors have been approved in different settings for patients with specific hereditary pathogenic variants, most notably homologous recombination repair pathways such as *BRCA1* and *BRCA2* genes.

The vast experience with PARP inhibitors (olaparib, niraparib, rucaparib) has been in the management of epithelial ovarian cancer (EOC). Studies first focused on the treatment of recurrent EOC and then their use as a maintenance strategy after platinum-based therapy. In 2020, ASCO published a comprehensive guideline on PARP inhibitor therapy in the management of EOC after ground-breaking studies in the first-line maintenance setting.[1] In 2022, a rapid update to the guidelines was issued to provide context to emerging survival data and revisions to the US Food and Drug Administration (FDA) indications, which occurred in the treatment setting and the maintenance therapy setting for the *BRCA1/2* wild-type population.[2] These are summarized in Table 1 and Figure 1.

The goal of this article is to highlight side effects of PARP inhibitors and focus on strategies to improve tolerance.

ADVERSE SIDE EFFECTS OF PARP INHIBITORS

It is challenging to obtain reliable real-world estimates of PARP inhibitor adverse events (AEs; frequency, grade) and dose modifications. It is likely that real-world events are similar to those reported in randomized clinical trials; however, given that strict eligibility criteria often lead to trial participants who are younger and fitter compared with community practice, it is possible that side effects are under-reported in clinical trials.[3]

The largest study of real-world experience was a longitudinal retrospective cohort analysis of the US MarketScan Commercial and Medicare Supplemental Databases.[4,5] The adverse effects were generally consistent with the safety reports from the randomized trials, which are, however, somewhat lower than those reported in clinical trials, as common toxicities (nausea, fatigue) may not be recorded in health care claims data unless severe enough for medical intervention. There are inherent limitations of such studies because of potential biases with using health care data, which are recorded for billing as opposed to research purposes. Dose reductions were required in 23%, 35%,

Author affiliations and support information (if applicable) appear at the end of this article.

PRACTICAL APPLICATIONS

- It is important to be proactive and take care to prevent and/or reduce the likelihood and impact of adverse effects associated with poly (ADP-ribose) polymerase (PARP) inhibitors. This could allow patients to continue treatment and potentially derive clinical benefit while enjoying good quality of life.
- The three approved PARP inhibitors (olaparib, niraparib, rucaparib) share several common adverse effects because of a class effect including nausea, fatigue, and anemia, but there are notable differences likely because of variations in their poly-pharmacology and off-target effects.
- Baseline doses may need to be modified on the basis of the PARP inhibitor being prescribed depending on renal and hepatic function and concomitant medications.
- Baseline dose reduction with niraparib is recommended for patients with platelet counts of <150,000/μL and/ a body weight of <77 kg.
- In patients with moderate renal impairment, olaparib should be started at a reduced dose of 200 mg twice a day, but dose reduction is not required for niraparib or rucaparib.

and 29% of patients on olaparib (n = 637), niraparib (n = 538), and rucaparib (n = 227), respectively, which are lower than those reported in clinical trials (Fig 2).[5] For example, in the PRIMA trial of maintenance niraparib after response to first-line chemotherapy, 71% of participants required a dose reduction, which was similar to the 66% requiring a dose reduction in the NOVA trial of maintenance therapy in participants with platinum-sensitive recurrent ovarian cancer after response to chemotherapy.[6,7]

An alternative source of real-world data is national databases of adverse drug reactions (ADRs) that are reported to regulatory authorities by clinicians even if they are uncertain whether there is a causal link with the drug.[8,9] However, only a minority of ADRs are reported and may underestimate important AEs.[9-11] Nonetheless, data repositories such as the FDA adverse event reporting system (FAERS) designed to support postmarketing surveillance provide important insights into ADRs including rare events that may not be observed in clinical trials.[8] Our discussion and commentary are based on the key adverse effects reported in the pivotal ovarian cancer clinical trials that led to the regulatory approvals for olaparib, niraparib, and rucaparib, but we also highlight relevant safety data including postmarketing reporting of ADRs that have emerged from real-world experience and provide guidance on management.

There have not been any head-to-head comparisons of PARP inhibitors in randomized trials, and we can only perform cross-comparison on the basis of the reported literature. They appear to be equally effective at least on the basis of comparison of hazard ratios across trials for similar indications in ovarian cancer.[12] The three approved PARP inhibitors for ovarian cancer share several common adverse effects because of a class effect including nausea, fatigue, and anemia, but there are also some notable differences likely because of variations in their polypharmacology and off-target effects.[11,13,14] They exhibit different binding affinities to PARP isoforms and may also inhibit transporters, kinases, and ion channels to a greater or lesser extent.[11,14,15] Rucaparib appears to be associated with higher incidence of adverse drug reactions reported probably because of many off-target effects.[11] There is high interindividual variability in pharmacokinetic exposure levels observed with olaparib, rucaparib, and niraparib, which could also account for some of the variability in adverse effects observed between patients as higher levels of exposure appear to be associated with greater toxicity, particularly hematologic.[13,14,16]

TABLE 1. PARP Inhibitors: FDA Indications (March of 2023) for Epithelial Ovarian Cancer[a]

Maintenance Therapy	PARP Inhibitor
First-line maintenance after response to platinum-based chemotherapy for newly diagnosed, advanced-stage, high-grade ovarian cancer	Olaparib (germline or somatic deleterious *BRCA* alteration) Olaparib with bevacizumab (germline or somatic deleterious *BRCA* alteration and/or HRD score positive) Niraparib (all—any *BRCA* or HRD status)
Second- or greater-line maintenance after response to platinum-based chemotherapy for recurrent platinum-sensitive ovarian cancer	Olaparib (all—any *BRCA* or HRD status) Rucaparib (all—any *BRCA* or HRD status) Niraparib (germline or suspected germline *BRCA* deleterious alteration)

Abbreviations: FDA, US Food and Drug Administration; HRD, homologous recombination–deficient; PARP, poly (ADP-ribose) polymerase.
[a]Of note, change in FDA approvals (as of March of 2023): (1) withdrawn indications for maintenance: second- or greater-line maintenance after response to platinum-based chemotherapy for recurrent platinum-sensitive ovarian cancer—niraparib in nongermline *BRCA* is no longer FDA-approved in this setting and (2) withdrawn indications for treatment—olaparib, rucaparib, and niraparib are no longer FDA-approved in this setting.

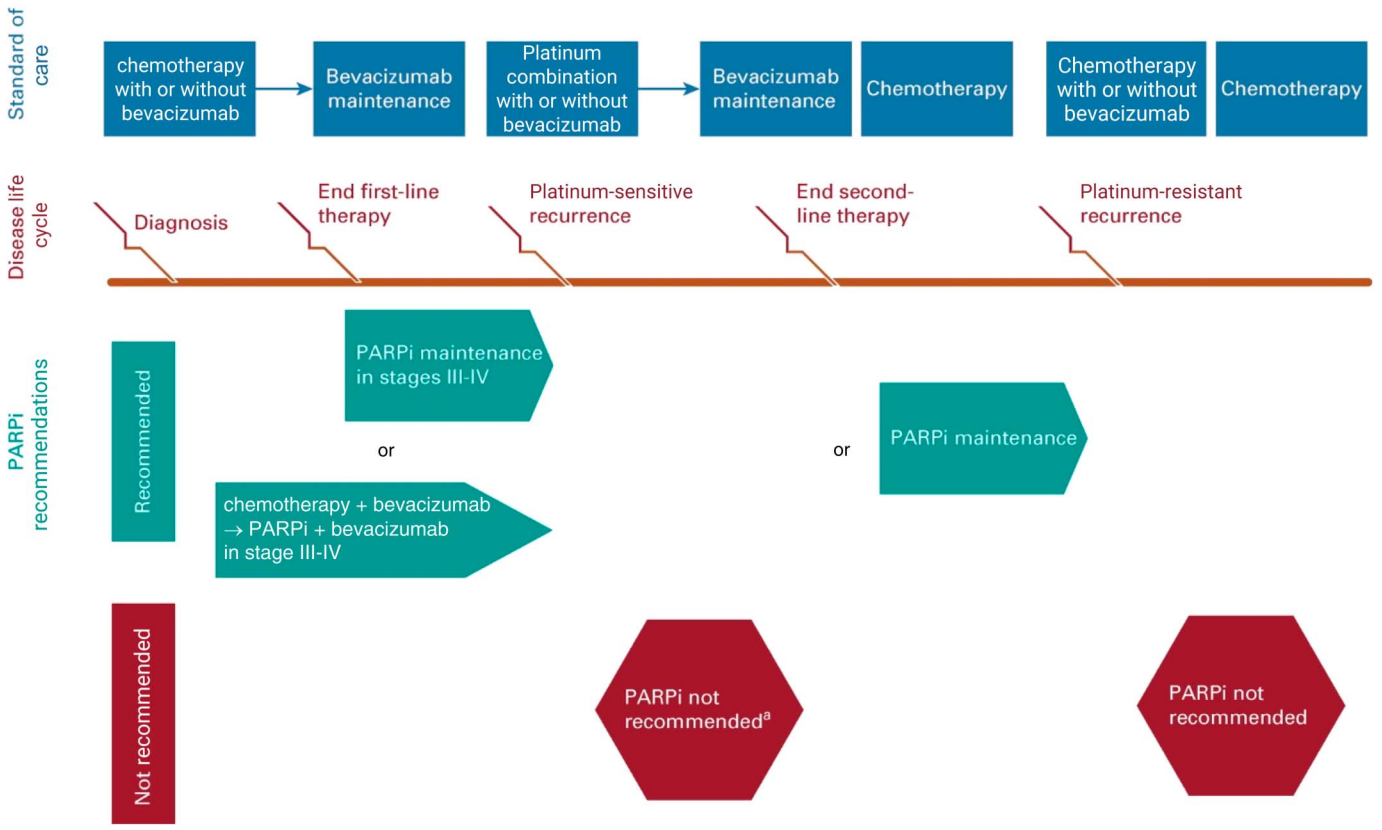

FIG 1. PARPi treatment indications: summary from ASCO rapid update guideline PARPi (Tew et al[2]). PARPi, poly (ADP-ribose) polymerase inhibitor. [a]Evidence on PARPi use as treatment in platinum-sensitive recurrence is evolving and data are continuing to emerge. Any decision to proceed with PARPi treatment in select populations should be based on individualized patient and provider assessment of risks, benefits, and preferences.

The defining characteristics of the three PARP inhibitors are summarized in Table 2 and 3 lists the frequency of AEs reported in the registration clinical trials, whereas Figure 2 lists the frequency of dose interruptions, reductions, and discontinuations in different disease settings.[4,6,7,17-23] Table 4 lists the recommended management for common AEs associated with PARP inhibitors. It is challenging to interpret the adverse effects reported in all clinical trials as they are typically presented in dense tables and include a long list of adverse effects including grading documented by clinicians over the long duration of the clinical trial. It is not possible to ascertain the timing, duration, and trajectory over time of the adverse effects from these tables or determine how they individually affect adherence and tolerability. Furthermore, it is important to acknowledge that there may be significant discordance in the frequency and grading of adverse effects reported by patients and clinicians.[24]

This article is not intended to be a definitive source for detailed prescribing information, or all the possible adverse effects associated with PARP inhibitors, but rather a summary of the more common and important adverse effects and approaches to their management. There are several excellent papers published on this topic, which are referenced for interested readers.[25-30] In addition, comprehensive prescribing information is provided by the pharmacologic companies for each of the approved PARP inhibitors. It is beyond the scope of this review to include adverse effects associated with PARP inhibitors combined with other agents.

SAFE PRESCRIBING AND STRATEGIES TO REDUCE THE LIKELIHOOD OF ADVERSE EFFECTS

First and foremost, it is important to be proactive and take care to prevent and/or reduce the likelihood and impact of adverse effects associated with PARP inhibitors. This could allow patients to continue treatment and potentially derive clinical benefit while enjoying good quality of life. It is essential to ensure that the patient is fully educated and well informed before commencing a PARP inhibitor and understands the potential benefits, as well as the possible adverse effects, and what is recommended to mitigate adverse effects. In addition, the patient should be made aware of the importance of close surveillance particularly in the first 12 weeks when many of the adverse effects occur such as nausea, vomiting, and hematologic toxicities including anemia and thrombocytopenia and require prompt intervention and management (Table 4).

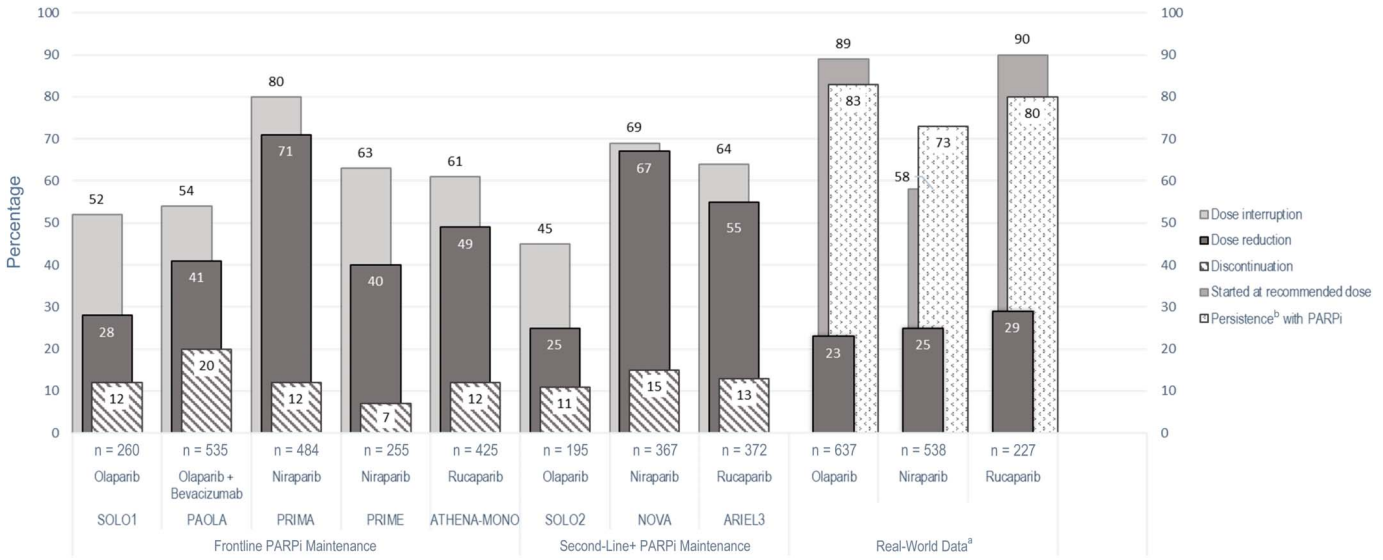

FIG 2. Dose interruptions, reduction, and discontinuation in studies of PARPi in frontline and second-line onward maintenance settings and real-world data. PARPi, poly (ADP-ribose) polymerase inhibitor. [a]Real-word data reported by O'Malley et al.[5] [b]Persistence was defined as the percentage of patients with no index PARPi regimen treatment gaps of >90 days of those with at least 6 months of continuous enrollment.

There are several factors to take into consideration before commencing a patient on maintenance treatment with a PARP inhibitor including the choice of PARP inhibitor, the starting dose, and when to commence maintenance therapy. Ideally, the patient should have recovered as much as possible from chemotherapy and should not start treatment <28 days after a last cycle chemotherapy to allow bone marrow recovery. The clinical trials allowed patients to commence maintenance therapy within 8-12 weeks depending on the trial.[6,7,17,19,22,23] In SOLO2, the predictors for reduced dose intensity included nausea at baseline and a performance status of 1 and delaying the start of treatment until symptoms are controlled would be prudent in such patients.[31] In NOVA, a weight of <77 kg and platelet counts of <150,000 μL were associated with greater hematologic adverse effects with 300 mg, once daily of niraparib, and this has led to recommendations to commence niraparib at 200 mg, once daily in patients who fit these criteria.[32,33] In the maintenance trials of PARP inhibitors in ovarian cancer, patients typically had to meet eligibility criteria including a hemoglobin of ≥10.0 g/dose level with no blood transfusion in the past 28 days, an absolute neutrophil count of ≥1.5 × 10^9/L, a platelet count of ≥100 × 10^9/L, a total bilirubin level of ≤1.5 × upper limit of normal (ULN), and a serum creatinine level of ≤1.5 × ULN. These eligibility criteria should be kept in mind when prescribing a PARP inhibitor. Although there is more flexibility in clinical practice than in clinical trials, it would be prudent to adhere as closely as possible to these criteria in practice.

Doses may also need to be modified on the basis of the PARP inhibitor being prescribed depending on renal and hepatic function and concomitant medications (Table 2). For example, in patients with moderate renal impairment, olaparib should be started at a reduced dose of 200 mg twice a day, but dose reduction is not required for niraparib or rucaparib.[13,14] Olaparib and rucaparib appear to be safe in patients with moderate hepatic impairment, but it is recommended that niraparib is reduced to 200 mg, once daily.[13,34] There are no data in patients with severe hepatic impairment, and it is advisable to avoid PARP inhibitors if this is the case. It is particularly important to take note of all concomitant medications as there may be important drug-drug interactions particularly in patients on olaparib.[35] Olaparib is primarily metabolized by CYP3A, and rucaparib is primarily metabolized by CYP2D6 and, to a lesser extent, by CYP1A2 and CYP3A4, whereas niraparib is metabolized by carboxylesterases.[35] Inhibitors or inducers of CYP3A4 may interact with olaparib, and the dose of olaparib should be reduced if being coadministered with a strong or moderate CYP3A4 inhibitor.[36] If a strong CYP3A inhibitor must be coadministered, the recommended olaparib dose reduction is to 100 mg, twice daily; if a moderate CYP3A inhibitor must be coadministered, the recommended olaparib dose reduction is to 150 mg, twice daily. The patient should be carefully monitored for AEs. Strong or moderate inducers of CYP3A4 should be avoided in patients on olaparib. There are good sources that can provide guidance on which drugs could interact with olaparib.[35,36] Dietary recommendations are also required for, in particular, advising patients on olaparib to avoid Seville oranges, starfruit, and grapefruit as they inhibit CYP3A4J5.[13,14] In addition, over-the-counter medications such as St John's

TABLE 2. Specific Characteristics of PARP Inhibitors

PARP Inhibitors	Olaparib	Niraparib	Rucaparib
Chemical structure			Target	PARP-1, PARP-2, and PARP-3	PARP-1 and PARP-2	PARP-1, PARP-2, PARP-3
Formulation	Tablet[a]	Capsule	Tablet
Dose forms	150 mg, 100 mg	300 mg, 200 mg, 100 mg	300 mg, 250 mg, 200 mg
Storage	2°C-30°C	Up to 25°C	20°C-25°C
Method of administration	Swallowed whole, with or without food	Swallowed whole, with or without food	Swallowed whole, with or without food
Starting dose	300 mg BD	200 mg daily; or 300 mg daily if the weight is ≥77 kg or the platelet is ≥150,000/μL	600 mg BD
Dose adjustment because of AEs	DL-1: 250 mg BD DL-2: 200 mg BD DL-3: discontinue	If starting dose at 200 mg daily, DL-1: 100 mg daily DL-2: discontinue If starting dose at 300 mg daily, DL-1: 200 mg daily DL-2: 100 mg daily DL-3: discontinue	DL-1: 500 mg BD DL-2: 400 mg BD DL-3: 300 mg BD DL-4: discontinue
Mean terminal half-life	15 hours	36 hours	25.9 hours
Metabolism	CYP3A4	Carboxylesterase and conjugation (UDP-glucuronosyltransferases)	CYP2D6, CYP1A2, CYP3A, CYP2C9, and CYP2C19 substrates
Drug-drug interactions	CYP inhibitors,[b] CYP inducers[c]	NA	CYP inhibitors,[d] CYP inducers[d] Multidrug and toxin extrusion transporters (MATE-1, MATE-2K) Organic ion transporters (OCT1, OCT2)
Drug-food interactions	Grapefruit, star fruit, pomegranate, and seville oranges[e]	NA	NA
Elderly (older than 65 years)	No adjustments in starting dose, limited clinical data in patients older than 75 years	No adjustments in starting dose, but greater sensitivity of some older individuals cannot be ruled out	Safety data unknown
Renal adjustment	CrCl 51-80 mL/min: no adjustment CrCl 31-50 mL/min: 200 mg BD CrCl < 30 mL/min: not recommended	CrCl 30-89 mL/min: no adjustment Severe impairment/on dialysis: safety data unknown	CrCl 30-89 mL/min: no adjustment Severe impairment/on dialysis: safety data unknown
Hepatic adjustment	Child-Pugh grade A or B: no adjustment Child-Pugh grade C: not recommended	Mild impairment[f]: no dose adjustment Moderate impairment[f]: 200 mg daily Severe impairment[f]: safety data unknown	Mild impairment[f]: no dose adjustment Moderate—severe impairment[e]: safety data unknown

Abbreviations: AE, adverse event; BD, twice daily; DL, dose level; NA, not available; PARP, poly (ADP-ribose) polymerase; ULN, upper limit of normal.

[a]Olaparib is also available as 50 mg capsule formulation; however, this is not to be substituted with olaparib tablets on a milligram-to-milligram basis because of differences in the dosing and bioavailability of each formulation.

[b]Coadministration with strong or moderate CYP3A inhibitors is not recommended. If a strong CYP3A inhibitor must be coadministered, the recommended olaparib dose reduction is to 100 mg, twice daily; if a moderate CYP3A inhibitor must be coadministered, the recommended olaparib dose reduction is to 150 mg, twice daily. The patient should be carefully monitored for AEs.

[c]Coadministration with a strong or moderate CYP3A inducer is not recommended. The efficacy of olaparib may be substantially reduced if coadministered with strong or moderate CYP3A inducer.

[d]Strong CYP3A4 inhibitors and inducers are not recommended. Dose adjustment should be considered for CYP1A2, CYP2C9, and CYP3A4 substrates with a narrow therapeutic window. CYP1A2 or CYP2D6 inhibitors did not affect rucaparib exposure.

[e]These fruits are known to inhibit CYP3A4 and may increase olaparib plasma concentration.

[f]Mild hepatic impairment was defined as total bilirubin ≤1.5× ULN and any AST level, or bilirubin ≤ULN and AST > ULN; moderate hepatic impairment was defined as total bilirubin >1.5 to 3.0 × ULN and any AST; severe hepatic impairment was defined as total bilirubin >3.0 × ULN and any AST.

NOTE. AEs with ≥10% G3 reported are given in italics, and AEs with ≥25% all grade reported are given in bold.

Abbreviations: AE, adverse event; CEI, clinical events of interest; G3, grade 3; NR, no response.

[a]Musculoskeletal pain includes arthralgia, backpain, pain in extremity, myalgia, and other related terms.

[b]Acute kidney injury includes blood creatinine increased, blood urea increased, and renal failure.

TABLE 4. Recommended Management for Common AEs Because of PARP Inhibitors[a]

General approach	Ensure that the patient has adequately recovered from chemotherapy; aim to start maintenance PARP inhibitor within 8-12 weeks of last cycle of chemotherapy Consider potential drug interactions with PARP inhibitors, which may affect the starting dose or choice of PARP inhibitor Proactively educate patients about the range of possible AEs, action plans, and frequency of investigations Implement close surveillance particularly in the first 12 weeks of treatment when AEs commonly occur	
AE	**Low-Grade Symptoms (or initial management)**	**High-Grade Symptoms (or follow-up management)**
Nausea with or without vomiting	Do not replace vomited dose; take next dose at scheduled time Consider prophylactic metoclopramide 30-60 minutes before PARP inhibitor and taking with a light meal Treat gastroparesis and dyspepsia when indicated Consider antiemetics such as metoclopramide or 5-HT3 antagonist for symptom management Consider taking PARP inhibitor later in the day (10 AM instead of 8 AM) at twice daily dose schedule or at night before bed for daily dose schedule (niraparib)	Dose interruption until AE resolves to grade 1 or less Exclude other causes (partial or complete bowel obstruction) Resume the same dose with prophylactic antiemetic therapy Dose reduction if AE recurs despite prophylactic therapy
Fatigue	Encourage a balance of physical activity and energy conservation. Tailor realistic expectations with structured daily routine Consider nonpharmacologic intervention: massage therapy and psychosocial interventions Optimize treatment for depression, sleep dysfunction, and nutritional deficit	Dose interruption until AE resolves to grade 1 or less Exclude anemia, electrolyte imbalance, or endocrine dysfunction as the contributing cause Exclude depression as a contributor Resume the same dose or consider dose reduction if AE recurs despite supportive management
Anemia	Workup investigations to exclude other causes of anemia including iron, vitamin B12, folate deficiencies, or hypothyroidism Consider a short period of dose interruptions without dose reduction	Dose interruption when Hb $<$ 8 g/dL, and bloods should be monitored weekly until Hb returns to $\geq$9 g/dL Blood transfusion is recommended when Hb $<$ 7 g/dL or higher levels if symptomatic or significant comorbidities are present Once recovered, resume PARP inhibitor at the same or reduced dose level (if dose interruption took place because of symptomatic anemia) If AE not recovered after 4 weeks or repeated occurrence, the patient should be referred to a hematologist to exclude MDS/AML
Neutropenia	Observe asymptomatic cases	Dose interruption when the neutrophil count is $<1.0 \times 10^9$/L, and bloods should be monitored weekly until recovery Once recovered, resume PARP inhibitor at a reduced dose level If AE is not recovered after 4 weeks or repeated occurrence, the patient should be referred to a hematologist to exclude MDS/AML
Thrombocytopenia	Review concomitant medications to exclude other causes of thrombocytopenia For niraparib Ensure that weight-based dosing was used for those $<$77 kg Dose interruption when the platelet count is $<100 \times 10^9$/L, and bloods should be monitored weekly until the platelet count is $\geq 100 \times 10^9$/L For olaparib and rucaparib, Dose interruption when the platelet count is $<50 \times 10^9$/L, and bloods should be monitored weekly until the platelet count is $\geq 100 \times 10^9$/L	Platelet transfusion recommended when the platelet count is $<10 \times 10^9$/L or higher if bleeding or on anticoagulants For niraparib: dose reduction if the platelet count falls to $<75 \times 10^9$/L or higher if bleeding For olaparib/rucaparib: dose reduction if the platelet count falls to $<50 \times 10^9$/L or higher if bleeding If AE is not recovered after 4 weeks or repeated occurrence, the patient should be referred to a hematologist to exclude MDS/AML

Abbreviations: 5-HT3, 5-hydroxytryptamine-3; AE, adverse event; MDS, myelodysplastic syndrome; PARP, poly (ADP-ribose) polymerase.
[a]It is important to refer to prescribing information for guidance on dosing, dose interruptions, and dose reductions for each PARP inhibitor.

Wort, which is among the most commonly used herbal medications in the United States, should be avoided as it is an inducer of CYP3A4. It is important to take care in the choice of antibiotics if required later in patients on olaparib because of potential drug-drug interactions (eg, ciprofloxacin, erythromycin) and a pharmacist should be consulted if in doubt. There is also a risk for drug-drug interactions when rucaparib is coadministered with substrates of multidrug and toxin extrusion transporters MATE-1 and MATE-2K and the organic ion transporters OCT1 and OCT2 such as metformin.[13,35] It is suggested that dose adjustments and close monitoring of patients on rucaparib should be considered for CYP 1A2, CYP2C9, and CYP3A4 substrates particularly for drugs with a narrow therapeutic index such as theophylline.[37]

MANAGING ADVERSE EFFECTS OF PARP INHIBITORS

GI Adverse Effects

A recent meta-analysis of phase II and III randomized trials with PARP inhibitors across all cancer types found that PARP inhibitors significantly increased the risk of all-grade nausea, vomiting, diarrhea, and decreased appetite although not constipation.[38] Patients with ovarian cancer have a higher risk of all-grade nausea and vomiting compared with other cancers for reasons that are unclear.[39] There is a paucity of real-world data on the incidence of GI side effects with PARP inhibitors apart from relatively small single-institution reports, which mirror the experience in clinical trials. There is a tendency to report only severe adverse effects in the FAERS or similar reporting systems in other countries, and it is likely that GI side effects would be underreported in them.[40]

Nausea and vomiting. Nausea and, to a lesser extent, vomiting are among the most common adverse effects associated with all the three FDA-approved PARP inhibitors (olaparib, niraparib, and rucaparib) in patients with ovarian cancer and thought to be mediated through off-target kinase inhibition.[41] They are a class effect and reported in over 75% of patients although grade 3 or 4 nausea and vomiting are uncommon at 1%-2% (Table 3). According to National Comprehensive Cancer Network (NCCN) guideline criteria, they would all be considered moderately high emetogenic agents although they are quite different from chemotherapy on which the guidelines are based.

Nausea typically occurs within the first few days to weeks of starting treatment, is usually low grade in most patients, and lessens and/or resolves over time although it may persist in a subset.[25] In patients who only develop these symptoms of nausea and vomiting after the first 3 months of starting treatment, alternative causes such as tumor progression should be excluded. The median time to first onset of nausea with olaparib tablets in the SOLO1 trial was 4 days (range, 0.03-21.49 months), and the median duration was 1.4 months.[42] The median time to first onset of vomiting was 1.46 months (range, 0.03-20.60 months), and the median duration was 2 days.[42] Relatively few patients discontinue PARP inhibitors because of nausea or vomiting, and proactive efforts should be taken to prevent and treat nausea and vomiting given the high incidence across all studies. In SOLO1, 3% of patients discontinued olaparib because of nausea, which was similar in the placebo arm (2%), and 1.9% ceased because of vomiting.[17] Nonetheless, even low-grade nausea and vomiting can affect quality of life particularly if persistent, and it is therefore important to educate and inform the patient of these adverse effects including the time course and trajectory over time, the approaches to mitigate them, and strategies to prevent or lessen their impact.

There have not been any controlled trials of antiemetics in patients treated with PARP inhibitors, and guidance is based on expert opinion and experience (Table 4). First and foremost, supportive treatment including antiemetics for prophylaxis and treatment are usually effective and dose interruption and dose reduction were only required in 5% of patients in SOLO1 for nausea and in none for vomiting.[17,42] Antiemetics such metoclopramide or domperidone or olanzapine are usually sufficient in most patients, whereas serotonin 5-hydroxytryptamine-3 receptor antagonists may be of value in selected patients for a short duration but are commonly associated with constipation. There are anecdotal reports that pyridoxine (vitamin B6), which is commonly used for pregnancy-associated nausea and vomiting, may be effective in some patients and is cheap and safe.[43] Dexamethasone is rarely used if ever needed and ideally avoided. The neurokinin-1 receptor antagonist aprepitant should be avoided with olaparib as it is a CYP3A4 inhibitor and can interact with it.[13,25] Anecdotally, advising patients to take the PARP inhibitor with food or shortly after eating and administering a prokinetic agent such as metoclopramide 30-60 minutes before the PARP inhibitor can help prevent or reduce nausea, which is prevalent in the first few weeks of starting treatment.[25,27-29] In patients on niraparib, which is administered once a day, taking the capsules at night before bed may be associated with less nausea and may be complemented by taking metoclopramide 30 minutes before if needed. In some patients with troublesome nausea, dose interruptions can be helpful and if ongoing despite antiemetics, dose reductions are usually effective. Patients who had dose reductions for any reasons in clinical trials could not re-escalate to the starting dose, whereas this may be considered in clinical practice for adverse effects such as nausea or vomiting although it would be ill advised if the dose reduction was for grade 3 or 4 anemia or thrombocytopenia.[44] It should be noted that recent analyses showed no adverse outcomes with respect to progression-free survival in patients with protocol-mandated dose reductions or interruptions for adverse effects.[31]

Other GI AEs. There are several other GI adverse effects including reduced appetite, dysgeusia constipation, diarrhea, abdominal pain, and symptoms of reflux. These can differ between the three PARP inhibitors (Table 3). For example, there was more constipation with niraparib on the basis of ADR reports in the United Kingdom.[11] These adverse effects can be managed effectively on the basis of standard practice, for example, proton pump inhibitors or prokinetic agents such as metoclopramide for reflux symptoms, laxatives for constipation, and loperamide for diarrhea. GI symptoms may also herald recurrence of ovarian cancer and include cramping abdominal pain, bloating, nausea, and vomiting.

Fatigue

Fatigue is a very common adverse effect associated with all PARP inhibitors and has been reported to occur in up to 60%-70% of patients with most having low-grade fatigue.[45] For example, in SOLO1, 64% of patients reported any-grade fatigue compared with 42% on placebo, with 4% of patients having grade 3 or 4 fatigue on olaparib and 2% on placebo.[42,46] Perhaps more important than the percentage of patients reported to have fatigue over the duration of the trial are the timing, duration, and trajectory over time. This was analyzed by Colombo et al[42] who reported that about 40% of patients experienced fatigue at 1 month after starting olaparib, which was mostly low grade, but importantly persisted over 2 years and was about twice as high as a placebo.

Interestingly, the findings are somewhat different from the responses of patients in SOLO1 to the question (GP1) in functional assessment of cancer therapy - ovarian, "I have a lack of energy," which could be considered as a surrogate for fatigue. Almost 80% of patients on olaparib reported lack of energy compared with 70% on placebo, which was mostly mild-moderate in both groups with a similar number of patients reporting more severe symptoms in the olaparib and placebo arms over 2 years.[47] These data underscore the high prevalence and impact of fatigue/lack of energy in ovarian cancer survivors including those not on a PARP inhibitor and the need to address this symptom. It is beyond the scope of this review to cover management in detail, but approaches include exercise programs and cognitive behavioral therapy as well as excluding reversible and treatable causes such as anemia, hypothyroidism, and depression. Insomnia is also very common in ovarian cancer survivors and could exacerbate symptoms of fatigue (see Table 4 and NCCN guidelines).[48]

Hematologic Adverse Effects

Hematologic adverse effects including anemia, neutropenia, and thrombocytopenia are common with all the PARP inhibitors, but there are some notable differences between them.[49] A recent meta-analysis that included over 9,000 patients enrolled in 29 randomized controlled trials reported that PARP inhibitors significantly increased the risk of all-grade anemia (risk ratio (RR), 2.32; 95% CI, 1.78 to 3.01; $P < .00001$), neutropenia (RR, 1.69; 95% CI, 1.38 to 2.07; $P < .00001$), and thrombocytopenia (RR, 2.54; 95% CI, 1.87 to 3.45; $P < .00001$).[49] Inhibition of PARP-2, in particular, as well as PARP trapping, is believed to be responsible at least in part for the hematologic toxicities.[30,50] In addition, thrombocytopenia may also be related to the volume of distribution (Vd) and bone marrow exposure, which could explain the higher risk of thrombocytopenia with niraparib as it has a Vd value of 1,074/L compared with 420/L for rucaparib and 158/L for olaparib.[14]

Close monitoring of patients particularly in the first 12 weeks after commencing a PARP inhibitor is required as hematologic adverse effects usually occur early but not invariably, and regular blood counts should continue while patients are on treatment. Anemia is the most common hematologic toxicity observed with PARP inhibitors and typically is macrocytic, and although it is not due to folate or B12 deficiency, grade 3/4 anemia was observed in 22% of patients on olaparib, 27% of patients on rucaparib, and 31% of patients on niraparib in the first-line maintenance therapy ovarian cancer trials.[6,17-19] Anemia should be managed with dose interruptions and dose reductions if dose interruption for symptomatic anemia is required. Transfusions should be used if the hemoglobin level falls to <7 g/dL accompanied by a dose reduction (Table 4).

Thrombocytopenia is also an important adverse effect. All-grade thrombocytopenia was observed in 11% of patients in SOLO1, 24% in ATHENA, and 46% in PRIMA.[6,17,19] More importantly, grade 3 or 4 thrombocytopenia was reported in 29% of patients in the PRIMA trial, 7% in ATHENA, and 1% in SOLO1.[6,17,41] Given the high incidence of thrombocytopenia with niraparib, it is recommended that patients with baseline platelet counts of <150,000/μL and/ a body weight of <77 kg should be treated with a reduced dose of 200 mg, once daily instead of 300 mg, once daily as they appear to have a higher risk of thrombocytopenia.[32] In the PRIME trial, which is a first-line maintenance trial of niraparib vs placebo that was performed in China, the incidence of grade 3 or 4 thrombocytopenia was 14% using the reduced dose of niraparib according to the above criteria.[21] It is worth noting that in the PRIME trial, which used individualized starting doses of niraparib, 40% of patients commenced on 200 mg, once daily still required further dose reductions. The median time to first dose reduction or interruption was 29 days. Dose reductions did not compromise patient outcomes.[51]

The niraparib prescribing information advises that patients should have weekly full blood counts in the first month of starting niraparib as thrombocytopenia typically occurs early, then monthly for the next 11 months, and periodically

thereafter.[52] If the platelet count falls to $<100 \times 10^9$/L, niraparib should be discontinued until the platelet count increases to above 100,000/μL, and if it falls to $<75 \times 10^9$/L, it should be restarted with a dose reduction once the level rises to >100,000/μL, provided that the count has recovered within 28 days (Table 4). The prescribing information also recommends platelet transfusions if the platelet count drops to $<10 \times 10^9$/L. If patients are on anticoagulants or antiplatelet agents, then consider interrupting these agents and have a lower threshold for platelet transfusions. Thrombopoietin receptor agonists such as avatrombopag have been reported to rapidly mitigate niraparib-associated thrombocytopenia and, in a small case series, enabled patients to continue therapy.[53] The dose interruption criteria are somewhat different with olaparib and rucaparib, and prescribing recommendations are that treatment should be temporarily discontinued only if the platelet count falls $<50 \times 10^9$/L and recommenced once it has recovered at either the same dose or a dose reduction depending on how low and how long the thrombocytopenia persists, with guidance provided in prescribing information for each agent. Close monitoring is recommended for platelet count between 50-75 $\times 10^9$/L, and dose interruption can be considered at the clinician's discretion.

Grade 3/4 neutropenia is common (20% with niraparib in PRIMA; 9% with olaparib in SOLO1, and 15% with rucaparib in ATHENA), and febrile neutropenia is rare.[6,17-19] Grade 3 or 4 neutropenia is managed with dose interruption until the platelet count recovered to $>1.5 \times 10^9$/L and dose reduction as well. Growth factors are not required.

Cardiovascular Adverse Effects

The most important cardiovascular adverse effect is hypertension. Niraparib is the only PARP inhibitor reported to cause hypertension, which may be due to an off-target inhibition of the kinase DYRK1A, which may increase levels of neurotransmitters in the dopaminergic system.[54] Hypertension was reported in 17% of patients in the PRIMA trial, with only 6% being grade 3 or greater.[6] The median time to first onset was 43 days in PRIMA, and there were no discontinuations because of hypertension. Hypertension can be managed with antihypertensive agents, but care should be taken to ensure that blood pressure is well controlled before commencing niraparib in patients with a history of hypertension. On commencing niraparib, blood pressure should be monitored regularly, at least weekly for the first 2 months, then monthly for the first year, and periodically thereafter. It should be noted that rare cases of hypertensive crises were reported postmarketing and could develop as early as within the first month of niraparib. In cases of hypertensive crisis or medically significant hypertension that cannot be adequately controlled with antihypertensive therapy, niraparib should be discontinued.[55]

Arrhythmias including tachycardia and palpitations have also been reported with niraparib. Postmarketing ADR reports include rare cases of hypotension with olaparib and rucaparib and arrhythmias with rucaparib.[8,11]

Neurologic Adverse Effects

Headaches have been reported in between 20% and 25% of patients treated with olaparib, niraparib, and rucaparib (Table 3). However, the incidence is similar to that reported in the placebo arms of all the trials. For example, in SOLO1, headache was reported in 23% of patients on olaparib and 24% on placebo and was in the majority low-grade and likely incidental rather than related.[17] Rarely, psychiatric adverse effects have been reported in postmarketing reports including mania, anxiety, and depression.[36,37,52] They have been reported with all PARP inhibitors although there was a trend suggesting that they may be higher with niraparib, which may be due to its higher blood brain barrier penetration. Posterior reversible encephalopathy syndrome has been reported with niraparib in 0.1% of patients treated and can occur in association with hypertension or with normal blood pressure during the first month of niraparib.[52] The diagnosis should be suspected in patients who present with seizures, headaches, cortical blindness, or visual disturbance and should be confirmed with an magnetic resonance imaging. This is potentially life-threatening, and niraparib should be ceased and not restarted.[55]

Laboratory Abnormalities That May Occur on PARP Inhibitors

There are a number of abnormal nonhematologic laboratory results that may occur in patients on PARP inhibitors and can vary depending on the PARP inhibitor. An elevated creatinine (grade 1 or 2) is observed in 10%-15% of patients on olaparib and rucaparib although not niraparib. This is due to inhibition of renal transporter proteins such as MATE 1 and MATE 2 and does not necessarily imply a decline in glomerular filtration rate or require dose modification, but alternative causes should be excluded.[56,57] Rucaparib is commonly associated with elevated levels in ALT/AST, with elevated levels occurring in just over 40% of patients in ATHENA-MONO.[19,57] These mostly grade 1 or 2 and transient but grade 3 or 4 elevations occur in 10%, which requires dose interruptions until levels are grade 2 or lower and dose reduction. Elevated ALT/AST is also observed in about 11% of patients treated with niraparib but almost always low grade. Dose interruption/reductions are not required for grade 1 or 2 elevations in ALT/AST. Elevated cholesterol levels are common with rucaparib, but grade 3 or 4 is reported in only 2%-4% of patients.[57] Statins may be required depending on the level and other risk factors.

Myelodysplastic Syndrome and AML

Treatment-related myeloid neoplasms (t-MNs), myelodysplastic syndrome (MDS), and AML are the most significant and clinically important adverse effects that have been

associated with PARP inhibitors. A recent meta-analysis that included 5,693 patients treated with a PARP inhibitor and 3,406 with placebo reported that PARP inhibitors increased the risk of MDS and AML with an overall risk of 2.63 (CI, 1.13 to 6.14; $P = .026$).[58] The incidence of MDS/AML was 0.73% across all PARP inhibitors compared with 0.47% in controls. The risk is related in part to the number of previous lines of chemotherapy, with a lower incidence of MDS/AML observed in the first-line maintenance trials compared with the recurrent setting. In SOLO1, which has the longest follow-up of all the first trials, one additional case was reported in the 7-year follow-up since the primary analysis in 2018 in the olaparib arm and 1 case in the placebo arm.[59] The overall incidence of MDS/AML was 1.5% in the olaparib arm (n = 260) and 0.8% in the placebo arm (n = 130) in SOLO1.[59] Similar findings have been reported in PAOLA, PRIMA, and ATHENA-MONO.[6,19,20] By contrast, the 5-year follow-up of SOLO2 reported that 8% of 195 patients were diagnosed with MDS (5%) or AML (3%) compared with 4% treated with placebo (n = 99).[22] Some of the patients in the placebo arm were diagnosed with AML/MDS after receiving subsequent chemotherapy and a PARP inhibitor.

The authors of the meta-analysis referred to above also interrogated the WHO pharmacovigilance database, which included 178 cases of MDS/AML, and looked at median treatment duration, latency, presenting features, and outcomes. There was clinical information available for only about 30% of cases; the median treatment duration was 9.8 months, the median latency period since first exposure and diagnosis of MDS/AML was 17.8 months, and the mortality was 45% in the 104 cases.[58]

Delayed cytopenia after the first 3 months of commencing a PARP inhibitor with pancytopenia, bicytopenia, or thrombocytopenia may be an early safety signal and identify patients at potential risk of t-MNs.[60] There is evidence to suggest that pre-existing TP53 clonal hematopoiesis of indeterminate potential variants before commencing a PARP inhibitor may be associated with t-MN and that in patients with cytopenias, the risk of t-MN is increased in the presence of these variants.[61] Clinicians should be alert to this possibility, treatment should be interrupted, and a hematologic consultation and bone marrow biopsy are advised. Conventional cytogenetics is recommended as about 30% of cases of t-MN may not meet morphologic dysplasia criteria as reported in a comprehensive study from France.[60] Complex karyotypes, frequent TP53 mutations, and a high rate of mutations in DNMT3A and TET2 are commonly observed.[62] The mortality of MDS and AML is high and a devastating consequence of treatment. It is beyond the scope of this review to discuss the management of patients with t-MNs.

Pneumonitis

PARP inhibitors have been linked to a risk of pneumonitis, most notably with olaparib and niraparib. According to a recent meta-analysis involving 5,771 patients treated with a PARP inhibitor (or control), PARP inhibitors increased the risk of pneumonitis with the Peto odds ratio of 2.68 (95% CI, 1.31 to 5.47; $P = .007$).[63] In patients treated with a PARP inhibitor, the incidence of all-grade pneumonitis was 0.79% (28 of 3,551), whereas it was 0.24% (5 of 2,060) in those treated with control.[63] The median time to event onset for pneumonitis associated with PARP inhibitors was 81 days, with most cases occurring during the first 6 months of treatment (IQR, 27-131).[63] The diagnosis should be suspected in patients with unexplained shortness of breath and confirmed on radiologic investigations where the features are consistent with interstitial lung disease.[64] Treatment includes cessation of the PARP inhibitor and commencement of corticosteroids.

Cutaneous Toxicities

All three of the licensed PARP inhibitors have been associated with cutaneous toxicities, but only the ARIEL3 trial specifically reported incidence of rash (12%, n = 46 of 372), pruritus (13%, n = 47 of 372), any-grade photosensitivity reactions (17%, n = 64 of 372), and peripheral edema (10%, n = 39 of 372).[23,25] There were only a few grade 3 AEs (1% or less), and the toxicities were mainly low grade.[23] When starting PARP inhibitor therapy, it is important to alert patients to the possibility of photosensitivity and to consider sun protection using sunscreen and hats and liberal use of skin moisturizers when appropriate.

SPECIAL POPULATIONS

Older Age

Women older than 65 years are under-represented in clinical trials, and there is a paucity of data on the efficacy and safety of PARP inhibitors in older patients. Only 20% of patients in SOLO2 were older than 65 years and met eligibility criteria to be enrolled in the trial limiting interpretation of analyses of safety and efficacy.[65] However, there did not appear to be any differences in dose interruptions and dose reductions in older patients or any safety signals. By contrast, very different findings were reported in ARIEL 3, which reported higher incidence of grade 3 toxicities in patients older than 65 years (70% *v* 54%) and higher percentage of dose reductions (71% *v* 47%) and dose discontinuations (21% *v* 12%) in older patients versus younger.[66] In PAOLA, patients older than 70 years had higher rates of grade 3 or 4 anemia and grade 3 or 4 neutropenia and higher incidence of severe hypertension than patients younger than 70 years.[67] A recent meta-analysis that included 4,364 patients enrolled in eight phase III trials of PARP inhibitors demonstrated that they were as effective in patients older than 65 years as in younger patients.[68] Safety information was limited to hematologic toxicities that were available in only a subset of patients and suggested that there may be a higher risk of thrombocytopenia in older patients. It

has been suggested that geriatric assessment should be considered in older patients before commencing a PARP inhibitor, which we agree with.[69] Real-world studies of PARP inhibitors in older populations are required as participants in clinical trials may not be representative.

Ethnicity

White patients dominate the patient populations enrolled into most trials of PARP inhibitors, and it is possible that there might be differences in safety and efficacy in different ethnic and racial groups. However, on the basis of limited information, it appears that safety and tolerability of PARP inhibitors are similar in Asian populations to White populations although there is a trend toward higher incidence of hematologic adverse effects, but this is an area that requires more research.[70]

CONCLUSIONS

PARP inhibitors are playing an increasingly important role in the treatment of EOC and breast, prostate, and pancreatic cancers, particularly in patients with pathogenic variants in *BRCA1* and *BRCA2* but also among those with other mechanisms of homologous recombination deficiency. The benefits and the adverse effects associated with PARP inhibitors have been very well documented in clinical trials, but less well so in real-world settings. Patients included in clinical trials are often younger with a good performance status and less comorbidities than the real-world population, and hence, the potential benefits and adverse effects of treatment with PARP inhibitors may not be superimposable in older patients or those with medical comorbidities or those who are on medications that might have precluded them from entry onto clinical trials. It is incumbent on us as clinicians to be aware of the long list of potential adverse effects associated with PARP inhibitors and to ensure that where possible they are prevented or mitigated and managed effectively. It is also imperative to educate and inform patients and their families about what to expect including the potential adverse effects including their timing, trajectory, and treatment and stress the importance of close monitoring in the first few months of starting treatment with appropriate management of adverse effects as outlined above. Awareness of the potential for drug-drug interactions as well as identifying those patients at greater risk of adverse effects is important and affects the choice of PARP inhibitor, the starting dose, and intensity of follow-up. Meticulous attention to all these factors is likely to improve tolerability and permit patients to continue treatment. It appears that the adverse effect profile will be less with the next generation of selective PARP1 inhibitors[71] but for the foreseeable future, we need to focus on the PARP inhibitors that we have access to in clinical practice and take the effort to understand how best to use them and how to avoid and manage the adverse effects.

Antibody-Drug Conjugates in Gynecologic Cancer

Hannah C. Karpel, MS[1]; Sachia Stonefeld Powell, JD[2]; and Bhavana Pothuri, MD, MS[3]

Overview

The present article reviews the current evidence for antibody-drug conjugates (ADCs) in gynecologic cancer. ADCs consist of a highly selective monoclonal antibody for a tumor-associated antigen and a potent cytotoxic payload conjugated through a linker. Overall, the toxicity profiles of ADCs are manageable. Ocular toxicity is a known class effect of some ADCs and is managed with prophylactic corticosteroid and vasoconstrictor eye drops as well as dose interruptions/holds and dose modifications. In ovarian cancer, mirvetuximab soravtansine, an ADC targeting alpha-folate receptor (FRα), received US Food and Drug Administration (FDA) accelerated approval in November 2022 after data from the single-arm phase III SORAYA trial. A second ADC targeting FRα, STRO-002, received FDA fast track designation in August 2021. Multiple studies with upifitamab rilsodotin, an ADC comprising a NaPi2B-binding antibody, are underway. In cervical cancer, tisotumab vedotin, an ADC-targeting tissue factor, received FDA accelerated approval in September 2021 after the phase II innovaTV 204 trial. Tisotumab vedotin in combination with chemotherapy and other targeted agents is currently being evaluated. Although there are no currently approved ADCs for endometrial cancer, there are many under active evaluation, including mirvetuximab soravtansine. Trastuzumab-deruxtecan (T-DXd), an ADC targeting human epidermal growth factor receptor 2 (HER2), is currently approved for HER2-positive and HER2-low breast cancer and shows promise in endometrial cancer. Like all anticancer treatments, the decision for a patient to undergo therapy with an ADC is a personal choice that balances the potential benefits with the side effects and requires thorough and compassionate support of their physician and care team and shared decision making.

INTRODUCTION AND ANTIBODY-DRUG CONJUGATE STRUCTURE

Treatment of gynecologic cancers is becoming more targeted with biomarker-directed therapy. For example, in ovarian cancer, three poly (ADP-ribose) polymerase (PARP) inhibitors are approved for patients with *BRCA* mutations or homologous recombination deficiency after progression on multiple lines of therapy or in the maintenance setting for newly diagnosed cases.[1] In cervical cancer, the US Food and Drug Administration (FDA) approved the immune checkpoint inhibitor (ICI) pembrolizumab in 2021 for use in combination with chemotherapy, with or without bevacizumab (monoclonal antibody against vascular endothelial growth factor), for recurrent or metastatic tumors expressing PD-L1.[2] In endometrial cancer, pembrolizumab was FDA approved in 2022 for advanced tumors that are microsatellite instability-high (MSI-H) or mismatch repair deficient (dMMR).[3] Recent updates in 2023 for the RUBY trial and GY-018 trial offer promise to move checkpoint inhibition into the first-line treatment of endometrial cancer.[4,5] Despite these advancements, additional strategies are needed to more specifically target tumor antigens and enhance drug delivery directly to the tumor.

A promising new treatment modality for cancer is the use of antibody-drug conjugates (ADCs), which have been FDA approved for breast cancer, lymphoma, multiple myeloma, gastric, and ovarian cancer.[6,7] ADCs combine the tumor-targeting capabilities of monoclonal antibodies with cytotoxic agents. There are three components to ADCs: (1) a highly selective monoclonal antibody for a tumor-associated antigen, (2) a potent cytotoxic agent designed to induce cell death when internalized in the tumor cell, and (3) a linker that is stable in circulation and releases the cytotoxic agent in target cells.[8,9] In this review, we will focus on the most promising ADCs for the treatment of ovarian, cervical, and endometrial cancer while staying mindful of the decisions the patient faces.

Overview of ADC Components: Antigen and Antibody

The target antigens should be present on the cell surface so that the ADC can find them and have high expression on tumor cell but not on normal tissue. For example, the protein human epidermal growth factor receptor 2 (HER2) is expressed up to 100 times more in tumor than in normal cells.[10] Additionally, the target antigens should be internalized so that the ADC can be transported into the cell. Once in the cell, proteases digest the antibody to

Author affiliations and support information (if applicable) appear at the end of this article.

PRACTICAL APPLICATIONS

- Enhanced understanding of carcinogenesis and underlying molecular biology has accelerated drug development, and antibody-drug conjugates (ADCs) represent recent improvements in targeted therapies for gynecologic cancer.
- ADCs are currently Food and Drug Administration approved in ovarian and cervical cancer, with ongoing research to improve outcomes in various settings and in combination with other agents.
- Several ADCs show promise in endometrial cancer and continued subtype-specific research is necessary to determine the best therapeutic approaches.
- Careful monitoring of treatment-related adverse events, including class-specific eye toxicity, is necessary to mitigate serious side effects of ADCs.

release the cytotoxic agent, which causes apoptosis of the cancer cells.

Overview of ADC Components: Cytotoxic Payloads

The cytotoxic molecules used in ADCs tend to be microtubule-targeting and DNA-damaging agents. Microtubule-targeting agents are functional only in proliferating cells and induce cell death by inhibiting tubulin, disrupting microtubules, and arresting the cell cycle in the G2/M phase.[11] DNA-damaging agents function independent of cell cycle and are cytotoxic in both proliferating and nonproliferating cells. Next-generation ADCs are now using RNA polymerase inhibitors and other agents for the cytotoxic payloads.[12]

Overview of ADC Components: Linkers

To ensure that the cytotoxic payload is delivered once it enters the tumor, linker stability is essential.[13] Linkers are generally classified as noncleavable and cleavable. Noncleavable linkers are mainly covalently bonded and must be internalized into cells and broken down by lysosomes to release toxins. Cleavable linkers are those that are cleaved depending on intracellular circumstances, including acid pH levels, glutathione levels, or the action of lysosomal proteases.[14] Some cleavable linkers can also deliver the drug extracellularly, inducing a bystander effect in which nearby tumor cells without expression of the targeted antigen are killed. The bystander effect can be desired in heterogeneous tumors in which not all tumor cells express the selected antigen.[15]

TOXICITY PROFILE OF ADCs

General Safety

As ADCs become more common, understanding their toxicity profiles is important. Premature release of cytotoxic payloads into the bloodstream is associated with hematologic toxicity, hepatotoxicity, and gastrointestinal reactions.[16] Secondary damages due to immune responses partially induced by antibodies to ADCs are also reported.[17] Ocular toxicity, discussed in more depth below, is a known side effect of certain ADCs and a dose-limiting toxicity in some trials. A recent meta-analysis published in *Cancer* characterized treatment-related adverse events (TRAEs) reported in clinical trials of ADCs. Covering multiple types of ADCs in several cancer types, the analysis included reports from 169 clinical trials encompassing 22,492 patients. The overall incidence of TRAEs was 91.2%, with the most common being lymphopenia (53.0%), nausea (44.1%), neutropenia (43.7%), blurred vision (40.5%), and peripheral neuropathy (39.6%). The incidence of grade 3 or higher TRAEs was 46.1%, with the most common being neutropenia (31.2%), hypesthesia (23.3%), thrombocytopenia (22.6%), febrile neutropenia (21.2%), and lymphopenia (21.0%). The incidence of treatment discontinuation because of TRAEs was 13.2%, and the rate of fatal TRAEs was 1.3%.[18]

It is important to note the variability of TRAEs associated with different ADCs. Variability is driven by differences in payloads, antibody targets, and to a certain extent, the linkers. For example, neuropathy is most associated with ADCs that have MMAE payloads, such as tisotumab vedotin, likely due to the disruption of the interphase microtubule function.[16] However, not all ADCs that share the same payloads have the same common TRAEs. Target type also plays a role. ADCs that target HER2, such as trastuzumab-deruxtecan (T-DXd), are associated with pulmonary toxicities and cardiotoxicity.[17,18] Interstitial lung disease (ILD) and pneumonitis are the most common cause of treatment-related death in patients treated with ADCs.[18] Finally, as mentioned above, linker stability is important for the timely release of the payload from the antibody, and premature release can cause a broader toxicity profile. The toxicity profiles of the various ADCs used in gynecologic cancer are listed below.

Ocular Toxicity

Ocular toxicities are known effects specific to certain ADCs. Ocular toxicities are off-target effects as most antigens that are targeted by ADCs are not significantly overexpressed in the eye. However, with tisotumab vedotin, these are on-target ocular adverse events as tissue factor (TF) is expressed on the eye. Most commonly, patients experience reversible blurry vision and keratopathy, which can be managed with dose adjustments and/or treatment delays.[19] Prophylactic corticosteroid and vasoconstrictor eye drops

are useful to reduce frequency and severity of these adverse events. Ophthalmic examinations and appropriate referral to ophthalmology are necessary to mitigate new or worsening ocular signs.[20]

ADCs IN OVARIAN CANCER

Management of ovarian cancer is challenging because of its late diagnosis and high recurrence, with 5-year survival rates of around 45%.[21] First-line treatment consists of surgery and platinum-based chemotherapy, followed by maintenance therapies. Targeted therapies, including PARP inhibitors and bevacizumab, have improved ovarian cancer management in the past decade, but many patients will still recur and succumb to the disease.[22] ADCs are a promising approach in recurrent ovarian cancer to improve outcomes in this malignancy.

ADCs Targeting Alpha Folate Receptor

Alpha-folate receptor (FRα) is expressed in more than 80% of epithelial ovarian cancers and is associated with poor prognosis.[23-25] Mirvetuximab soravtansine is the first ADC to receive FDA accelerated approval in platinum-resistant ovarian cancer. Mirvetuximab soravtansine is an ADC comprising a FRα-binding antibody, a cleavable disulfide linker, and a tubulin-disrupting maytansinoid DM4 payload.[26] The FDA also granted approval of the FOLR1 RxDx assay to identify patients eligible for mirvetuzimab soravtansine with high levels of FRα expression, defined as ≥75% tumor cells staining with 2+ intensity.[27]

The FDA approval decision in November 2022 was supported by findings from the phase III global single-arm SORAYA trial, which enrolled 106 patients with platinum-resistant ovarian cancer whose tumors expressed high levels of FRα and who had been treated with one to three previous systemic therapies, one of which had to have included bevacizumab. The primary end point was confirmed objective response rate (ORR) as assessed by investigator, and the key secondary end point was duration of response (DOR). Participants received intravenous mirvetuximab soravtansine at 6 mg/kg once every 3 weeks until disease progression or unacceptable toxicity. Mirvetuximab soravtansine produced an ORR of 31.7% (95% CI, 22.9 to 41.6), including a 4.8% complete response rate and a 26.9% partial response rate. The DOR was 6.9 months (95% CI, 5.6 to 9.7). The most common TRAEs (all grade, grade 3+) included blurred vision (41%, 6%), keratopathy (36%, 9%), and nausea (29%, 0%). TRAEs led to dose delays in 32%, dose reductions in 19%, and discontinuations in 7% of patients.[28]

MIRASOL (ClinicalTrials.gov identifier: NCT04209855), the confirmatory phase III registration trial for mirvetuximab soravtansine to convert the accelerated approval to full approval, has completed accrual, and data are expected in 2023. Progression-free survival (PFS) of mirvetuximab soravtansine versus investigator's choice chemotherapy will be compared in patients with advanced platinum-resistant high-grade epithelial ovarian, primary peritoneal, or fallopian tube cancers that are FRα-high by immunohistochemistry percent staining 2+.[29] Additionally, the phase III randomized GLORIOSA trial (ClinicalTrials.gov identifier: NCT05445778) is ongoing and will evaluate mirvetuximab soravtansine in combination with bevacizumab maintenance versus bevacizumab alone as maintenance therapy after platinum-based chemotherapy for patients with FRα-high platinum-sensitive disease (Table 1).

STRO-002 also targets FRα and received FDA fast designation for ovarian cancer in 2021.[30] STRO-002 comprises the FRα-binding antibody SP8166 (H01), a cleavable protease linker, and a hemiasterlin-derivative payload. The hemiasterlin-derivative payload has a potentially dual mechanism of effect by both inhibiting tubulin and inducing an immunogenic response on cell death. Interim safety data of a phase I dose-expansion study of 15 patients with advanced ovarian cancer treated with a higher dose level of STRO-002 (5.4 mg/kg once every 3 weeks) along with prophylactic pegfilgrastim were recently reported. The higher starting dose led to greater patient benefit than the lower dose (4.3 mg/kg once every 3 weeks), with an ORR of 43.8% compared with an ORR of 31.3%. Safety data were consistent with previous findings with 85.5% of TRAEs grades 1 or 2 and no ocular toxicity. At the higher dose, prophylactic pegfilgrastim led to reductions in grade 3 or higher neutropenia compared with the patients not given prophylactic pegfilgrastim.[31] From these data, the registration-directed phase II/III REFRaME study will be initiated later this year. Additionally, STRO-002-GM2 (ClinicalTrials.gov identifier: NCT05200364) is a phase I multicenter dose-escalation study to assess STRO-002 in combination with bevacizumab in patients with advanced ovarian cancer that is refractory or has relapsed after standard therapy.

Finally, MORAb-202 (farletuzumab ecteribulin) is an ADC comprising the FRα-binding antibody farletuzumab conjugated to the cytotoxic inhibitor eribulin mesylate through a cleavable linker. A phase I dose-escalation trial in FRα-positive solid tumors had a 75% disease control rate, including one complete response and two partial responses in the nine patients with ovarian cancer.[32] From these initial data, MORAb-202 0.9 mg/kg (cohort 1) and 1.2 mg/kg (cohort 2) once every 3 weeks were chosen as doses for the expansion part of Study 101 in patients with FRα-positive tumors (defined as >5% of cells stained at 1+ to 3+ intensity level). In patients with platinum-resistant ovarian cancer, the ORR was 25.0% (95% CI, 9.8 to 46.7) in cohort 1 and 52.4% (95% CI, 29.8 to 74.3) in cohort 2. ILD/pneumonitis was the most common TRAE and was of low-grade severity in most patients. Antitumor activity was observed across

TABLE 1. ADCs in Gynecologic Cancer

ADC	Target	Linker	Payload	Status	Ongoing Trials
Ovarian					
Mirvetuximab soravtansine	FRα	Sulfo-SPDB (disulfide linker)	DM4	FDA accelerated approval	MIRASOL

Abbreviations: ADC, antibody-drug conjugate; AF-HPA, auristatin F-hydroxypropylamide; DM4, N2′-deacetyl-N2′-(4-mer-capto-4-methyl-1-oxopentyl)-maytansin; FDA, US Food and Drug Administration; FRα, alpha-folate receptor; HER2, human epidermal growth factor receptor 2; mc-val-cit-PABC, maleimidocaproyl-L-valine-L-citrulline-p-aminobenzyl alcohol; MMAE, monomethyl auristatin E; NaPi2B, sodium-dependent phosphate transport protein 2B; SN-38, 7-ethyl-10-hydroxy-camptothecin; Trop2, trophoblast cell surface antigen-2; Val-Cit-PABA, L-valine-L-citrulline-p-aminobenzoic acid.

varying FRα expression levels, and dose optimization is ongoing[33] (ClinicalTrials.gov identifier: NCT04300556).

ADCs Targeting NaPi2B

NaPi2B (sodium-dependent phosphate transport protein 2B) is expressed in two thirds of patients with high-grade serous ovarian cancer.[34] Upifitamab rilsodotin (UpRi) is an ADC comprising a NaPi2B-binding antibody, a cleavable ester linker, and an AF-HPA payload. The UPLIFT trial is a phase II, single-arm, registrational study of NaPi2B in platinum-resistant ovarian, fallopian tube, and primary peritoneal cancer with up to four previous lines of therapy. In promising preliminary results presented at the Society of Gynecologic Oncology (SGO) Annual Meeting 2022, the ORR for the 75 evaluable patients was 23%, and in those who were NaPi2B-high (n = 38), the ORR was 34%. In the NAPi2B-high cohort, the ORR was 44% in dose group 36 mg/m^2 versus 27% in dose group 43 mg/m^2. The most common TRAEs were fatigue, nausea, vomiting, pyrexia, and transient aspartate transaminase elevations. Lower frequencies and lower-grade pneumonitis occurred in dose group 36 versus dose group 43. Grade 3 or greater neutropenia, ocular toxicity, and peripheral neuropathy have not been observed.[35]

Two ongoing studies will shed light on UpRi in different settings. UPNEXT is a phase III study of UpRi versus placebo as maintenance therapy in recurrent platinum-sensitive high-grade serous ovarian cancer expressing high levels of NaPi2B (ClinicalTrials.gov identifier: NCT05329545). This trial is important not only because it focuses on platinum-sensitive cases but also because as maintenance therapy with bevacizumab or PARP inhibitors is moved to the frontline for ovarian cancer; there is no standard of care for patients treated with these agents who subsequently relapse. For example, if a patient receives a PARP inhibitor in the frontline setting, it is not clear if they could be rechallenged with another PARP inhibitor. Additionally, some comorbidities preclude current maintenance therapies. The UPNEXT trial will hopefully provide an additional maintenance option.[36] UPGRADE-A is a phase I dose-escalation and dose-expansion study to evaluate UpRi and carboplatin in recurrent platinum-sensitive high-grade serous ovarian cancer, followed by UpRi maintenance (ClinicalTrials.gov identifier: NCT04907968). This trial is

currently recruiting, and if positive and findings are confirmed, it could potentially provide another platinum doublet in the treatment of patients with platinum-sensitive recurrent ovarian cancer.

ADCs IN CERVICAL CANCER

Cervical cancer is the fourth most common cancer in women and has a 5-year survival rate of 67%.[37] Doublet chemotherapy (paclitaxel plus either platinum or topotecan) with bevacizumab (if eligible) is recommended for first-line treatment of recurrent or metastatic cervical cancer. Cervical cancer incidence and mortality has markedly decreased over the past few decades because of increased screening and vaccination practices against HPV. New treatments include targeted therapies, such as bevacizumab and pembrolizumab, as well as ADCs.[38]

ADCs Targeting TF

TF is the main initiator of the extrinsic coagulation pathway, and in cancer, it contributes to cell proliferation, survival, angiogenesis, and the epithelial to mesenchymal transition that promotes tumor development.[39,40] TF is highly expressed in cervical cancer (up to 90%-95%) and other solid tumors.[41-43] Tisotumab vedotin is an ADC comprising an anti-TF monoclonal antibody covalently linked to the microtubule-disrupting agent MMAE through a protease-cleavable linker.[44] This ADC was granted FDA accelerated approval in September 2021 for recurrent or metastatic cervical cancer with disease progression on or after chemotherapy.[45]

The decision for accelerated approval was supported by data from the single-arm, multicenter, phase II innovaTV 204 trial, which enrolled a total of 101 patients with recurrent and/or metastatic cervical cancer who experienced disease progression during or after doublet chemotherapy with bevacizumab (if eligible), had received two or fewer prior systemic therapies, and had an Eastern Cooperative Oncology Group performance status of 0 or 1. Patients were administered tisotumab vedotin at a dose of 2.0 mg/kg once every 3 weeks until disease progression or unacceptable toxicity. The primary end point was ORR per RECIST v1.1 criteria and independent imaging review committee assessment. Secondary end points included ORR per investigator assessment and RECIST criteria, overall survival (OS), and safety. Tisotumab vedotin resulted in a confirmed ORR of 24% (95% CI, 15.9 to 33.3) with 7% of responders experiencing a complete response and 17% a partial response. The median DOR was 8.3 months (95% CI, 4.2 to not reached). The median time to response was 1.4 months (range, 1.1-5.1), and activity was noted within the first two treatment cycles. Tisotumab vedotin had a manageable safety profile, with mostly mild-to-moderate adverse events. Grade 3 or higher TRAEs were reported in 28% and included peripheral neuropathies (7%), neutropenia (3%), fatigue (2%), ulcerative keratitis (2%), and bleeding (2%).[46]

InnovaTV 205/ENGOT-cx8/GOG-3024 is a global, randomized, multicohort phase Ib/II trial to evaluate tisotumab vedotin in combination with bevacizumab, pembrolizumab, or carboplatin. Interim safety and efficacy data from two dose-expansion cohorts were presented at European Society for Medical Oncology 2021. Of 33 patients treated with first-line tisotumab vedotin plus carboplatin (median five cycles), the confirmed ORR was 55% (95% CI, 36 to 72), and prespecified grade 3 or higher TRAEs included peripheral neuropathy (12%), ocular toxicity (3%), and bleeding (6%). Of 35 patients treated with second-line/third-line tisotumab vedotin plus pembrolizumab (median six cycles), the confirmed ORR was 35% (95% CI, 20 to 54), and prespecified grade 3 or higher TRAEs included peripheral neuropathy (3%), ocular toxicity (3%), and bleeding (9%).[47] At ASCO 2022, interim safety and efficacy results from a third dose-expansion cohort evaluating first-line tisotumab vedotin and pembrolizumab were reported. Of 33 patients treated as of the cutoff, the confirmed ORR was 41% (95% CI, 24 to 59), with 3 (9%) complete responses and 10 (31%) partial responses. The median PFS was 5.3 months (95% CI, 4.0 to 12.2), and the median OS was not reached. Prespecified grade 3 or higher TRAEs included peripheral neuropathy (3%), ocular toxicity (9%), and bleeding (6%).[48] This trial is ongoing (ClinicalTrials.gov identifier: NCT03786081). Finally, innovaTV 301/ENGOT-cx12/GOG-3057 is a global, randomized, open-label, phase III trial evaluating tisotumab vedotin versus investigator's choice of chemotherapy in patients with recurrent and/or metastatic cervical cancer who have progressed on one to two previous lines of therapy. The primary end point is OS, and the trial has completed accrual (ClinicalTrials.gov identifier: NCT04697628).

ADCs IN ENDOMETRIAL CANCER

Endometrial cancer is the most common and second deadliest gynecologic cancer in the United States, with rising incidence and mortality rates.[49] After the discovery of four molecular subtypes by The Cancer Genome Atlas and their influence on prognosis, treatment consideration by subtype is now recommended.[50] FDA-approved ICIs include pembrolizumab and dostarlimab for previously treated dMMR/MSI-H cases and pembrolizumab/lenvatinib for mismatch repair-proficient/microsatellite-stable cases.[51] ADCs are an active area of research within this molecularly focused landscape.

ADCs Targeting FRα

Although no ADCs are currently FDA approved in endometrial cancer, there are several promising agents. Like in ovarian cancer, FRα is overexpressed in endometrial tumors with approximately 64% of endometrial tumors positive for

FRα receptors.[52] However, despite promising preclinical data, clinical efficacy of the anti-FRα ADC, mirvetuximab soravtansine, has been less clear.[53] In a study of multiple solid tumors, there was a positive response in 2 of 11 (18.2%) endometrial tumors at a dose of 5 mg/kg once every 3 weeks.[54] A phase II trial is ongoing to evaluate mirvetuximab soravtansine in microsatellite-stable endometrial cancer (ClinicalTrials.gov identifier: NCT03835819). STRO-002 is also being evaluated in endometrial cancer in a phase I trial (ClinicalTrials.gov identifier: NCT03748186).

ADCs Targeting HER2

HER2, a receptor tyrosine-protein kinase encoded by *ERBB2*, is another potential therapeutic target for endometrial cancer therapy.

Immunohistochemistry studies show high HER2/neu expression in approximately 35% of patients with uterine serous carcinoma.[55,56] T-DXd is an ADC consisting of the anti-HER2 antibody trastuzumab and a topoisomerase I inhibitor payload combined by a cleavable tetrapeptide linker. This drug received accelerated FDA approval in 2019 for HER2-positive breast cancer, and following recent data from DESTINY-Breast04 which showed a 50% risk reduction in disease progression or death in cases with low expression of HER2 (PFS, 9.9 *v* 5.1 months; hazard ratio, 0.50; 95% CI, 0.40 to 0.63), it received accelerated approval for HER2-low breast cancer in August 2022.[57,58] ILD/pneumonitis occurred in 12.1% of patients who received T-DXd, and the most common TRAEs of grade 3 or higher were neutropenia (13.7%), anemia (8.1%), and fatigue (7.5%). The incidence of TRAEs associated with discontinuation of treatment and death, respectively, were 16.2% and 3.8% in the T-DXd group compared with 8.1% and 2.9% in the physician's choice chemotherapy group.[57]

As there is no standardized scoring system for HER2 expression in endometrial cancer, the use of ADCs such as T-DXd could be widely beneficial. Results from the STATICE trial evaluating efficacy of T-DXd in HER2-positive uterine carcinosarcoma showed a response rate of 55% and a PFS of 6.2 (95% CI, 4.0 to 8.8) months in HER2 2+/3+ patients. Grade 1-2 ILD occurred in 23.5% and Grade 3 ILD in 2.9% of patients.[59] Endometrial cancer is also being evaluated in the DESTINY-PanTumor02 trial using T-DXD in HER2-positive tumors (ClinicalTrials.gov identifier: NCT04482309). In HER2-positive serous endometrial cancer, combined T-DXd and olaparib (PARPi) is being evaluated (ClinicalTrials.gov identifier: NCT04585958). Finally, the FDA has granted fast track designation to DB-1303, an ADC comprising an anti-HER2 monoclonal antibody, a cleavable peptide-linker, and a topoisomerase I inhibitor. DB-1303 displayed favorable antitumor activity and safety in both HER2-positive and HER2-low tumor models and is under evaluation in an ongoing phase I/IIa trial (ClinicalTrials.gov identifier: NCT05150691) in patients with advanced/unresectable, recurrent, or metastatic endometrial cancer.[60]

ADCs Targeting Trophoblast Cell Surface Antigen-2

Trophoblast cell surface antigen-2 (Trop2) is a tumor-associated calcium signal transducer. ADCs targeting Trop2 have primarily been researched in breast cancer. However, preliminary findings suggest that it may be effective in gynecologic oncology as overexpression has been observed in ovarian (over 80%), cervical (over 80%), and endometrial (over 90%) cancers.[61-65]

Sacituzumab govitecan is an ADC comprising an anti-Trop2 monoclonal antibody conjugated to SN-38, the active metabolite of the topoisomerase I inhibitor irinotecan, through a cleavable linker.[66,67] Sacituzumab govitecan has a high drug-to-antibody ratio (7.6:1), and SN-38 is released extracellularly in the tumor microenvironment on hydrolysis of the linker, providing a bystander effect.[67,68] In a phase I/II basket trial, the ORR was 22.2% (95% CI, 6.4 to 47.6) in the endometrial cancer cohort (n = 18) at a dose of 10 mg/kg once daily on days 1 and 8 of a 21-day cycle. The median PFS was 3.2 months (95% CI, 1.9 to 9.4), and the median OS was 11.9 months (95% CI, 4.7 to not calculable). The safety profile was consistent with the overall basket study, and the most common TRAEs were nausea (83%), diarrhea (67%), fatigue (61%), vomiting (56%), decreased appetite (56%), and neutropenia (56%).[69]

THE PATIENT EXPERIENCE: WHAT MAKES TREATMENT WORTH IT?

> *"Cancer begins and ends with people. In the midst of scientific abstraction, it is sometimes possible to forget this one basic fact… Doctors treat diseases, but they also treat people, and this precondition of their professional existence sometimes pulls them in two directions at once."*
>
> June Goodfield, The Siege of Cancer

What makes treatment with an ADC, or any treatment, worth it to a patient? It depends on the patient. And, it may depend on the physician and care team.

Sachia Stonefeld Powell, an ovarian cancer survivor, knows because she's been there. "I was diagnosed with high grade serous ovarian cancer in early 2017 at the age of 50, with a recurrence in mid-2020, and I've had to make difficult decisions for which there was no clear *right* choice. Deciding what made a treatment option *worth it* required a thoughtful analysis; how many extra days of life the treatment will likely give me weighed against what the treatment will likely take away. And I relied on my oncologist to help find the right balance for me."

Whether a given treatment is worth pursuing may depend on the patient's understanding of the possible benefits. Will the

treatment cure them or at least buy enough additional time that other options may become available? Once complete, will the patient likely enjoy a lengthy break before the next treatment is required? A patient may also consider whether the therapy could provide enough time to reach a personal milestone, such as a family wedding or a significant birthday, or simply provide more time to watch children or grandchildren grow. Ultimately, how much hope does the treatment provide?

Whether a treatment is worth it also may depend on the cost to the patient, including time, money, and missed moments. Obstacles such as transportation, childcare, or financial hardship may discourage a patient from pursuing treatment. For those with the resources to address these hurdles, the impact on their quality of life may influence the decision. For example, the potential risk of ocular toxicities, common in ADCs, will likely affect a professional photographer far differently than a patient who relies less on their vision in daily activities. Similarly, the possibility of long-term or permanent side effects, such as neuropathy, and the time necessary to manage those side effects may discourage some patients from pursuing a treatment. A patient also may consider how much of the treatment will be covered by insurance and how much time will be spent fighting to obtain that coverage.

Whether a treatment is worth it may also depend on where the patient is in their cancer journey, including whether the patient and their support system can handle the additional burden—both physical and psychological. A patient who feels physically well may be more willing to take on the rigors of additional toxicities. A patient who is psychologically worn down may not be ready for the proverbial fight. And whether treatment is worth it may depend on the extent to which the patient and their support system have accepted the patient's own mortality.

A patient's internal values or external influences may also factor into the decision. Someone with a strong spiritual conviction may put their future into the hands of a higher power. Certain families or cultures may downplay illness, and patients from those backgrounds may be less willing to embark on a treatment that will bring attention to their disease. A treatment may seem worth it to a patient if it could help others—for example, if their clinical trial participation could help ensure better options for future survivors. In addition, some may be influenced by the experiences of other patients or by what they have read on the Internet.

In considering this myriad of factors, the patient naturally relies on their physician and care team; the choice may well depend on the physician counseling of the treatment, how well it is explained, and how enthusiastically it is endorsed. How well the physician explains the efficacy of the treatment and in what terms (ie, PFS, OS, etc) affect what the patient takes away from the conversation. Several studies have shown that shared decision making improves health-related quality of life.[70-72] However, in a web-based survey of more than 14,000 ovarian cancer survivors conducted by the SGO Ovarian Cancer National Alliance, there was a disconnect between patients and physicians regarding expectations for PFS, OS, and acceptable treatment-related toxicities.[73] Continued efforts by the oncology community to personalize the balance between efficacy and toxicity for individual patients are needed. Choice of treatment also likely depends on what the patient actually hears, which may be limited by their emotional state, their reluctance to ask questions, cultural or linguistic barriers, or overall health literacy. Ultimately, the decision may be influenced by how much the patient trusts the physician and care team to be honest and forthcoming with them and to view them as a whole person and not just a disease.

For some patients, maintaining the best possible quality of life will guide their decision while for others longevity prevails. For some, the choice to pursue a particular treatment may be crystal clear; for others, it may be a heart-wrenching decision. For us all, it is a balance of many factors that are deeply personal. As patients, we look to the physician and care team to help balance what the treatment will give against what it will likely take and to help us formulate our plan.

What makes treatment worth it? It depends.

Current Treatment Strategies and Risk Stratification for Oral Carcinoma

Issa Mohamad, MD[1]; Mica D.E. Glaun, MD[2]; Kumar Prabhash, MD[3]; Ahmed Busheri, MD[4]; Stephen Y. Lai, MD, PhD[2,5,6]; Vanita Noronha, MBBS, MD, DM[3]; and Ali Hosni, MBBCh, MSc, PhD[7]

overview

Management of oral cavity squamous cell carcinoma (OSCC) involves a multidisciplinary team approach. Surgery is ideally the primary treatment option for nonmetastatic OSCC, and less invasive curative surgical approaches are preferred in early-stage disease to minimize surgical-related morbidity. For patients at high risk of recurrence, adjuvant treatment using radiation therapy or chemoradiation is often used. Systemic therapy may also be used in the neoadjuvant setting (for advanced-stage disease with the intent of mandibular preservation) or in the palliative setting (for nonsalvageable locoregional recurrence and/or distant metastases). Patient involvement in treatment decision is the key for patient-driven management, particularly in clinical situation with poor prognosis, for example, early postoperative recurrence before planned adjuvant therapy.

INTRODUCTION

Oral cavity cancer (OCC) accounts globally for an estimated 377,000 new cases yearly (2% of all cancers) and over 177,000 deaths (1.8% of all cancers).[1] Almost 90% of these cancers are squamous cell carcinomas.[2] There are noticeable geographic disparities in the incidence of oral cavity squamous cell carcinoma (OSCC) with approximately two thirds of the cases occurring in the developing countries.[2] Tobacco use in all its forms, betel quid, and alcohol consumption are well-established risk factors of OSCC.[2,3] In recent years, there has been an increase in the prevalence of the disease among nonsmokers, suggesting that other factors may be implicated; however, further studies are required to identify these risk factors.[4] The majority of the patients with OSCC are presented with advanced disease, with relatively poor overall survival (OS).[5]

In principle, management of OSCC is decided by a multidisciplinary team after comprehensive, clinical, and radiographic review.[2] Surgery remains the primary treatment approach for OSCC.[6] However, morbid effects on cosmetic and functional outcomes related to the extent of disease and the required surgical resection emphasize the importance of using less invasive curative surgical approaches (eg, use of sentinel lymph node [SLN] biopsy) in early-stage disease to minimize surgical-related morbidity.[7] In addition, radiation therapy (RT) or chemoradiation (CRT) is usually added as an adjuvant treatment for patients with high risk for recurrence.[8] In some instances, RT/CRT can be the primary treatment modality, especially for patients who are unfit for surgery.[9] Early locoregional recurrence (LRR) and/or distant metastases (DM) are associated with worst prognosis in OSCC.[10,11] Systemic therapy is usually indicated in such cases; however, it can potentially be used in the neoadjuvant setting for patients with advanced-stage disease aiming for tumor reduction that may permit better functional and cosmetic outcomes (eg, mandibular preservation), while maintaining similar oncologic outcomes.[12,13]

SLN BIOPSY FOR EARLY-STAGE ORAL CAVITY CANCER

The use of SLN biopsy provides clinicians with a diagnostic procedure, which may be followed by an escalation of treatment (ie, completion neck dissection [CND]) when necessary. After multiple randomized control trials (RCTs), this diagnostic tool is now established as the standard of care for melanoma, breast cancer, and endometrial cancer.[14-20] Utilization of SLN biopsy for head and neck cancer (HNC) is under active investigation with appealing applications, particularly for stage I to II (cT1-2N0M0) OSCC.

Staging of OSCC requires imaging of the neck, with small nodes (under 1.1-1.5 cm) without adverse features considered to be clinically node-negative (cN0).[21,22] All larger nodes or those demonstrating adverse features should undergo ultrasound-guided fine needle aspiration biopsy to enable appropriate clinical staging before consideration of surgical management of OSCC in the neck.[23]

Patients with early-stage OSCC and clinically and radiographically negative neck have been found to have up to 20%-30% occult neck disease.[24,25] NCCN guidelines recommend proceeding with an elective neck dissection (END) for tumors with a depth of invasion (DOI) over 3 mm. Within this setting, up to 80%

PRACTICAL APPLICATIONS

- Sentinel lymph node biopsy–based clinical trials provide evidence for personalized neck management for oral cavity cancer (OCC).
- High-dose radiation (with concurrent chemotherapy) for OCC could be a reasonable alternative management strategy to primary surgery when it is not feasible and also for patients with early recurrence before the planned postoperative radiation.
- Identifying patients with OCC at high-risk distant metastases (DM) could allow (1) the risk-adaptive DM screening protocol with possible local ablative treatment of early-detected oligometastases and (2) future evaluation of novel systemic multiagent regimens in the setting of a clinical trial in the group of patients with high-risk DM.
- Induction chemotherapy can potentially be used with an aim of mandibular preservation for OCC after careful multidisciplinary discussion and patients' involvement in treatment decision.
- In the adjuvant setting for patients with OCC and high-risk features (positive margin and/or extranodal extension), the standard of care is cisplatin concurrently with radiotherapy. In cisplatin-ineligible patients, docetaxel with postoperative radiation is supported by the best evidence. Other possible options include concurrent cetuximab, carboplatin/5FU, carboplatin/paclitaxel, or the use of accelerated radiation.

of patients undergoing END for early-stage OSCC are ultimately found to be pN0.[26] SLN biopsy, if proven efficacious and sensitive for OSCC, may aid in reducing the morbidity and cost associated with END.

SLN Biopsy: Novel Diagnostic Framework

END has been the standard of care for OSCC. When comparing END to active surveillance with therapeutic neck dissection (TND) as needed, a landmark RCT of 500 patients concluded that disease-free survival (DFS) and OS had statistically significant improvements for the END cohort.[27] That said, this study did provide higher rates of adjuvant radiation to the END cohort given the availability of surgical pathology data, and the TND group may not have had rigorous active surveillance. Further study of management of OSCC with END compared with active surveillance with as-needed TND continues with JCOG1601 in Japan for patients with OSCC with a DOI of 3-10 mm.[28]

Although END is comprehensive and aggressive, regional recurrence continues for patients with pN0 OSCC with rates ranging from 9% to 18%.[29-32] Patients found to be pN1 using END have a similar regional recurrence rate of 20%.[32] Lending to the discussion of SLN biopsy utility, regional recurrence is often seen in the contralateral neck (30%-39%).[32,33]

Comparisons of SLN biopsy with END have been conducted, and investigations continue. In 2010, a multi-institutional phase II trial identified a 96% negative predictive value (NPV) for SLN biopsy in OSCC.[34] Similarly, in 2015, the Sentinel European Node Trial (SENT) identified SLN biopsy used for OSCC to have an 86% sensitivity for negative sentinel nodes.[35] This study confirmed that 70% of patients with early OSCC staged using SLN biopsy were able to avoid CND with a 3-year DFS of 92%. In addition, a National Cancer Database retrospective study revealed equal OS for SLN biopsy compared with END with a reduced hospital length of stay for patients undergoing SLN biopsy.[36] A multicenter RCT reported in 2020 performed by Garrel et al[37] with 307 patients with oral cavity and oropharyngeal cancer receiving either SLN biopsy or END revealed similar recurrence-free survival and OS with noninferiority margin at 10%. Similarly, an RCT published in 2021 by Hasegawa et al[7] of 275 patients revealed noninferiority, margin at 12%, in survival and postoperative complications. Multiple trials have subsequently shown SLN biopsy to be safe with patients deemed cN0 preserving a high NPV, disease-specific survival, and OS.[7,34,35,38-44] In addition, cost is reduced with SLN biopsy compared with END by an estimate of 23%.[41]

Identification of aberrant nodal distribution is a major potential advantage of SLN biopsy. One study identified up to 40% of patients revealing aberrant nodal drainage on preoperative lymphoscintigraphy.[39] Furthermore, contralateral drainage has been seen in 2%-17% of patients, most commonly with floor of mouth lesions.[29,39,45]

The NRG-HN006 is a phase II/III RCT currently comparing SLN biopsy and END in early-stage OSCC (ClinicalTrials.gov identifier: NCT04333537).[46] The coprimary end points are to determine whether patient-reported neck and shoulder function and related quality of life 6 months postoperatively is superior with SLN biopsy compared with END and to determine whether DFS is noninferior with SLN biopsy compared with END. Unlike previous studies with larger noninferiority margins (10%-12%), NRG-HN006 is based on a noninferiority hazard ratio (HR) for DFS (time to event) for an absolute difference of 5% in 2-year DFS rates.[46]

As definitive evidence is developing to address standard-of-care approaches to management of early-stage OSCC in the neck, certain considerations regarding patient selection, surgical technique, and postoperative surveillance must be considered.

Patient Selection

SLN biopsy remains a valuable diagnostic procedure. As such, performing SLN biopsy in patients with multiple comorbidities should not be performed as a means of reducing surgical burden given that an additional anesthetic event may become necessary in the event of a positive SLN for CND.

Proceeding with SLN biopsy in patients with previously treated HNC or lymphatic disease may be considered given the potential for mapping of aberrant nodal distribution patterns. This patient population has commonly been excluded from current investigative studies but definitely merit careful trial-based examination.

Patients' ability to engage in follow-up should be taken into consideration as well since negative SLN biopsy will require active surveillance with clinical and imaging examination every 3 months.[35] Patients unable to adhere to this follow-up pattern may not be ideal for SLN biopsy.

Tumor Selection

Given the anatomic variation within the oral cavity, tumor selection is critical for appropriate utilization of SLN biopsy for OSCC. Primary T1-2 tumors that can be reliably resected with appropriate margins without requiring neck access have been deemed appropriate for SLN biopsy.[35] Free flap reconstruction is often required for defects of the floor of mouth, retromolar trigone, palate, buccal mucosa, and gingiva, thus necessitating entry to the neck. Such lesions may be more appropriate for END given the need for neck vessel access for free flap reanastamosis.

The eighth edition of the American Joint Committee on Cancer (AJCC)/Union for International Cancer Control (UICC) Cancer Staging Manual includes DOI for OSCC as this increases the risk of metastasis. The current literature varies on DOI cutoff for SLN biopsy utilization with 10 mm, which is the highest limit. In 2015, Schilling et al[35] suggested the utility of SLN biopsy for tumors with DOI up to 10 mm. In 2021, Hasegawa studied SLN biopsy for tumors with DOI up to 4 mm.[7] Each millimeter of DOI increase has been associated with a potential increased risk of nodal metastasis, although there is clear variability depending on tumor thickness.[47]

Patients with a distinct lesion with biopsy revealing carcinoma in situ may have regions of invasive carcinoma on final pathology. As such, these patients may be considered for SLN biopsy.[48] Patient comorbidities and oral cavity status should be taken into consideration when selecting patients for SLN biopsy. Patients with a T1-2 lesion also presenting with immunologic deficit, pervasive dysplasia, and concern for field cancerization are less appropriate for SLN biopsy selection.[48] Future studies may elucidate whether the utilization of biomarkers in addition to DOI, such as CD44, may be helpful in predicting nodal metastasis.[49]

Surgical Considerations

Across specialties, SLN biopsy has proven to be operator-dependent with an expected learning curve.[42,50,51] Specific to OSCC, surgeons more experienced with SLN biopsy have been found to have an improved NPV.[34] Thus, surgeon credentialing and case review are critical components for prospective clinical trials.

The preoperative imaging and injection of OSCC lesions require multidisciplinary training and cohesion. The preferred radioisotope is technetium-99m (^{99m}Tc). The SLN is identified by a gamma count at least 10 times higher than background and with a count at least 10% of the hottest SLN. For oral cavity lesions, utilization of radiotracer and an optical tracer (eg, indocyanine green) may be helpful. Oral cavity subsites such as the floor of mouth may especially benefit from optical tracer use given the likelihood of shine through from radiotracer signal to the upper neck basin intraoperatively.

Appropriate pathologic analysis is critical for any SLN biopsy program. Step-sectioning at 150 μm is recommended.[52,53] This methodology increases the number of pathologic sections over 10 times compared with conventional lymph node assessment and has been shown to significantly upstage nodal involvement.[53] Given the increased pathology needs, the number of SLNs removed has been studied with recommendation for removal of 2-3 SLNs from the neck with over five SLNs rarely seen.[35,44,45,54]

Frozen section is not recommended in the SLN practice for breast cancer given its destructive nature. Of note, both Hasegawa et al and Garrel et al used frozen section and were able to identify 64%-68% positive SLNs with continuation to CND.[7,37] Most centers are not able to perform thin step-sectioning for frozen evaluation, and so a two-stage procedure is the most common practice.

Postoperative Surveillance

Patients with early OSCC and positive SLN biopsy results merit a CND. This includes proceeding with CND for micrometastases (<2 mm) and isolated tumor cells found on SLN biopsy. Patients with a negative SLN biopsy and those who have a CND merit active surveillance with the current recommendation for imaging (eg, ultrasound) and clinical examination every 3 months for the first 12-18 months.[48] This ensures that false-negative SLN biopsy cases are identified early to enable salvage surgery. Median time to recurrence has been reported at 9 months with no isolated neck recurrence seen after 24 months.[35]

Recommendation

Support for SLN biopsy is increasing through improved multicenter RCTs that provide evidence for personalized oncologic care. With appropriate techniques used, the addition of SLN biopsy for early-stage OSCC may provide comparable outcomes with END with potentially reduced morbidity and cost.

DEFINITIVE RADIATION THERAPY (ie, NONOPERATIVE MANAGEMENT) FOR ORAL CAVITY CANCER

In a substantial proportion of patients with OSCC, up-front curative-intent surgery may not be possible for one or more of the following reasons: (1) cancer-related factors (eg, unresectable tumor), (2) patient-related factors (eg, patient refusal to undergo surgery or those with old age, poor performance status [PS], or medical comorbidities with high operative risk), (3) treatment-related factors (eg, extent of curative-intent surgery will result in unacceptable local morbidity and unsatisfactory functional outcomes), and (4) health care system–related factors (eg, limited health care insurance or unavailable access to proper operative facilities and resources).[9] In these clinical scenarios, primary RT/CRT may be considered a potential alternative treatment choice for OSCC.[9]

In a subgroup analysis of 129 patients with advanced resectable OSCC/oropharyngeal carcinoma who were randomly assigned to either preoperative RT versus postoperative radiotherapy (PORT) versus definitive RT at an RTOG-7303 phase III RCT, there were no statistically significant differences in locoregional control (LRC; 43% *v* 52% *v* 38%, respectively, $P = .4$) or in OS (30% *v* 36% *v* 33%, respectively, $P = .8$).[55] Another RCT compared primary surgery with PORT versus definitive CRT (with cisplatin/fluorouracil [FU]) for stage III/IV HNC (n = 119; 27% were OSCC). There were no statistically significant difference in 3-year DFS (54% *v* 43%, $P = .4$) and 3-year OS (50% *v* 40%, $P = .6$).[56] However, these RCTs included a relatively small number of patients with OSCC, and the findings should be interpreted in the context of potential value of definitive RT/CRT as an alternative treatment approach for OSCC in settings when up-front primary surgery may not be possible.

Several retrospective studies assessed the effectiveness of primary RT or CRT for OSCC. Among published studies, the 5-year OS ranged from 0% to 78%.[9,57-62] A review and meta-analysis of patients with resectable OCC revealed that primary RT/CRT was linked to a significantly higher risk of death in early-stage disease (HR, 2.39; 95% CI, 1.56 to 3.67; I^2, 63%) and was not associated with a statistically increased risk of death (HR, 1.98; 95% CI, 0.85 to 4.64; I^2, 84%) in patients with advanced OSCC treated with CRT.[63] The reported 5-year local and regional control ranged between 53%-92% and 24%-92%, respectively, for patients with OSCC who underwent nonoperative management.[9,64-68] However, these studies included a wide range of variations in tumor characteristics, tumor site, stage, delivered RT techniques, and types of chemotherapy regimens administered.[9,57-62,69]

Recommendation

Definitive RT/CRT for OSCC could be a reasonable alternative management strategy to primary surgery when it is not feasible in view of patient, tumor, treatment, or health care system–related factors.

EARLY LOCOREGIONAL RECURRENCE BEFORE PLANNED PORT IN OSCC: RISK FACTORS AND SALVAGE TREATMENT

In the adjuvant setting, patients with OSCC are traditionally classified according to the risk of LRR into three main categories: (1) low-risk group (no adverse histopathologic features and no need for adjuvant therapy), (2) intermediate-risk group (presence of one or more adverse pathologic features [eg, pT3-4 category, pN2-3 category, close resection margin(s), etc] that indicate the need of PORT), and (3) high-risk group (patients with involved resection margin(s) and/or pathologic extranodal extension [pENE] that require postoperative CRT).[8] Moreover, previous studies showed that patients with OSCC and early recurrence had worse outcomes than those with late relapse, indicating that the timing of recurrence does really matter.[70] In a subgroup of patients with OSCC, LRR after curative-intent surgery could happen too early, even before the planned PORT, reflecting the aggressive behavior of the disease and alarming for complex postoperative treatment course and poor outcomes.[71] In a retrospective review of 601 patients with OSCC treated with PORT after curative-intent surgery, it was reported that 15% of patients with advanced OSCC developed early recurrence before the planned PORT. Oral tongue subsite, pT3-4 category, pN2-3 category, and microscopic positive resection margin were the risk factors for developing early recurrence.[71]

The diagnostic confirmation of early recurrence is challenging and adds to the complexity of such cases for two main reasons: (1) difficulty of clinical detection of early recurrence after surgery even with comprehensive head and neck physical examination and (2) possibility of delaying the planned PORT after performing nonroutine diagnostic procedures postoperatively with subsequent prolongation of the overall treatment package time (ie, from surgery to end of PORT), which can affect the oncologic outcomes.[70,72-74] Therefore, arranging postoperative imaging before RT planning is crucial for patients with higher risk of early recurrence. The ideal time of conducting such imaging is controversial; however, 4 weeks after surgery, it is acceptable to allow for postoperative changes to resolve and to avoid delay in the start of PORT.[72,75] The pathologic confirmation of early LRR is recommended to avoid unnecessary aggressive treatment.[76] However, performing such diagnostic tests would require patient engagement

and collaborative efforts between head and neck surgical and radiation oncologists along with imaging and pathology specialists to avoid delay in PORT.

Once the early recurrence is confirmed, intensified postoperative treatment strategies should be discussed with the patient by the multidisciplinary team members. Salvage treatment options include (1) additional revision surgery (if feasible); (2) use of intensified radiation by planning higher total radiation dose (≥66 Gy), higher radiation dose per fraction (hypofractionation), or accelerated PORT schedules[77-79]; and/or (3) addition of adjuvant systemic therapy concurrently with PORT.[8] The use of high-dose accelerated hypofractionated PORT (70 Gy/33 fractions, 66 Gy/30 fractions, or equivalent) with concurrent cisplatin (for patients who were fit [and agreed] to receive chemotherapy) in patients with OSCC and early recurrence has resulted in a successful salvage rate of 36% at 5 years after PORT; however, this rate was potentially lower for patients with large volume of early recurrent disease.[71]

Recommendation

Postoperative head and neck imaging before RT planning is recommended for patients with OSCC and higher risk of early recurrence (eg, oral tongue subsite, pT3-4 category, pN2-3 category, and microscopic positive resection margins). Treatment intensification with high-dose accelerated hypofractionated RT and concurrent cisplatin (for fit patients) could provide a successful salvage option for early recurrence in approximately one third of patients.

DISTANT METASTASIS IN ORAL CAVITY CANCER: PREDICTION AND POTENTIAL PREVENTION

As advances in treatment of OSCC have resulted in improved LRC,[68,80] more patients with OSCC are exposed to the risk of developing DM with a cumulative incidence ranging between 5% and 15%.[81-83] Several studies showed that predictors of DM in patients with OSCC included patient age, pT category, pN category, histological grade, lymphovascular invasion, and pENE.[56,70,71,73,81,84-86] These risk factors can be used to develop and validate a risk group classification of DM.

Identifying a higher-risk group for DM may have the potential to improve the outcomes of patients with OSCC. This could happen by evaluating imaging surveillance strategies to detect oligometastases in the defined high-risk group of DM at an earlier stage and subsequently assessing the oncologic outcomes after local ablative therapy for oligometastases. Meta-analysis of lung oligometastases in 403 patients with HNC (30% with primary OSCC) showed that lung SBRT or metastectomy was associated with better OS compared with systemic therapy or best supportive care only.[87]

Evaluation of intensified treatment for patients at high risk of DM at the time of initial surgery could also contribute to improve the outcome for OSCC. In a phase III RCT, patients with OSCC who were treated with preoperative chemotherapy (cisplatin and FU) followed by surgery with or without PORT had a lower (but not statistically significant) rate of 5-year DM as compared with patients who were treated with up-front surgery with or without PORT (4.1% *v* 9.3%).[88] In another phase III RCT, the use of chemotherapy (docetaxel, cisplatin, and FU) in the neoadjuvant setting showed a trend of improving the rate of DM (5.5% *v* 8.7%) compared with patients with OSCC who did not receive neoadjuvant chemotherapy; moreover, in subgroup analysis, only patients with cN2 disease had lower rates of distant metastasis-free survival (P = .043) with subsequent improvement in OS (P = .043) when received neoadjuvant docetaxel, cisplatin, and FU.[89]

Recommendation

Identifying patients with OSCC at high-risk DM could allow (1) risk-adaptive DM screening protocol with possible local ablative treatment of early-detected oligometastases and (2) future evaluation of novel systemic multiagent regimens in the setting of a clinical trial in the group of patients with high risk of DM, rather than the entire population with locally advanced OSCC.

INDUCTION CHEMOTHERAPY FOR MANDIBLE SPARING

The role of induction chemotherapy for organ preservation in advanced laryngeal and hypopharyngeal carcinomas is well-established.[90,91] Somewhat more controversial is the role of induction chemotherapy for organ preservation in advanced OSCC.[92,93] In OSCC that invades or abuts the mandible, surgical management has traditionally involved a mandibulectomy. However, mandibular resection is associated with long-term morbidities even after sophisticated reconstruction techniques, including impairment in speech and swallowing, cosmesis, body image, and QOL.[94-96] Preservation of the native mandible thus represents a worthwhile endeavor. Induction chemotherapy is one of the strategies used to shrink the tumor preoperatively and facilitate mandibular preservation.

Studies on Induction Chemotherapy for Mandibular Preservation

The potential purpose of induction chemotherapy in advanced OSCC is not to replace surgery with CRT but rather to decrease the extent of surgery permitting mandible preservation. Several studies have evaluated the role of induction chemotherapy in resectable locally advanced HNC. Ma et al performed a meta-analysis that included the data of 2,099 patients from 14 randomized studies that assessed induction chemotherapy in resectable HNSCC. They found that induction chemotherapy led to an 8% (95% confidence interval [CI], 1 to 16; P = .02) decrease in the rate of DM without significantly affecting the LRR rate, DFS, or OS.[97]

However, most of the studies on resectable HNSCC, including the study by Zhong et al[89] (which evaluated induction chemotherapy exclusively in patients with resectable OSCC), have not studied or reported the mandibular preservation rates. Table 1 provides the details of the studies that evaluated the utility of induction chemotherapy specifically for mandibular preservation in resectable OSCC. The primary end point in the study by Licitra et al was not organ preservation, and hence, this should be considered indirect supporting evidence for mandibular preservation. The study by Chaukar et al[13] is the best available evidence in this setting, although this was a phase II study. Definitive evidence of the efficacy of induction chemotherapy for mandibular preservation is currently under evaluation in a phase III RCT with mandibular preservation as the primary end point.[99]

Induction Chemotherapy Regimen

The study by Lictra et al was an older study, with recruitment between 1989 and 1999. The induction chemotherapy regimen was CF (cisplatin + FU). We now know that the addition of docetaxel to CF (DCF) induction chemotherapy potentially improves oncologic outcomes.[100,101] Accordingly, in the study by Chaukar et al, the more efficacious DCF induction chemotherapy regimen was chosen. The reported objective response rate from DCF in the study by Chaukar et al was surprisingly low (38%) compared with the response rate of 82% reported in the study by Licitra et al; however, the limitation of using radiologic response criteria to predict pathologic response was previously noted for advanced HNC postinduction chemotherapy.[102] Nevertheless, the mandibular preservation rate achieved in the study by Chaukar et al was reassuring and supports the choice of DCF as the induction chemotherapy regimen of choice.

Surgical Margins Postinduction Chemotherapy and Adjuvant Therapy

An important issue to consider when using induction chemotherapy, particularly in patients with borderline resectable or unresectable cancers, and for organ preservation, is whether to consider the preinduction chemotherapy margin status for surgical resection or to resect only the residual tumor volume postinduction chemotherapy. In the study by Licitra et al, the resection was planned according to the original tumor volume; however, the final surgical resection plan was left to the discretion of the operating surgeon, so long as a macroscopic 1.5 cm margin was obtained. Positive surgical margins were noted in 4 patients (4%) in the induction chemotherapy arm and 12 (12.4%) in the up-front surgery arm. Complete pathological remission or only microscopic residual tumor was noted in 27 patients (33%) who received induction chemotherapy. In a matched-pair analysis of patients with T4 buccal mucosa tumors who had received induction chemotherapy for technically unresectable disease (wide margins taken around the postinduction chemotherapy tumor volume) and those with T4 buccal mucosa tumors that were technically resectable and underwent up-front surgery (gross margin of 1 cm was taken around the tumor), the margin positivity rate reassuringly did not differ between the two groups.[103] Accordingly, in the study by Chaukar et al, the surgical resection margins were based on the postinduction chemotherapy tumor volume. To address the possibility of persistent residual microscopic tumor islands in case the tumor had shrunk nonconcentrically from induction chemotherapy, all patients in the induction chemotherapy arm received adjuvant cisplatin-based concurrent CRT, regardless of pathologic risk features. None of the patients in the study of Chaukar et al had positive margins, and the pathologic complete remission rate was 11.8% (n = 4). In both studies, there were no differences in LRR between the patients treated with up-front surgery with or without adjuvant therapy and those who received induction chemotherapy, suggesting that the approach taken by Chaukar et al may be appropriate for properly selected cases, that is, resection on the basis of the postinduction chemotherapy tumor volume, followed by adjuvant concurrent radiation with or without chemotherapy. Caution should be exercised at the time of planning the concurrent chemotherapy regimen, and the cumulative dose of cisplatin that the patient has received as part of the induction chemotherapy regimen should be calculated.

Complications of Induction Chemotherapy, Postsurgical Complications, and QOL

In the study by Licitra et al in which the induction chemotherapy regimen was three cycles of CF, 25 patients (25.5%) developed grade 3, 11 (11.2%) had grade 4, and 3 (3%) had grade 5 (fatal) toxicities. Common grade 3/4 toxicities included neutropenia in 18 patients (18.4%), mucositis in 8 (8.1%), nausea/vomiting in 7 (7.1%), and cardiac in 6 (6.2%). There was no difference in the surgical morbidities and the hospitalization times between the patients who received induction chemotherapy and those who had up-front surgery. In the study of Chaukar et al that used three cycles of DCF induction, 14 patients (41.2%) had grade 3 toxicities and 11 (32.4%) had grade 4 toxicities. Surgical morbidities occurred in 2 (5.9%) in the induction chemotherapy arm while no patients in the up-front surgery arm experienced surgical complications. Thus, with all the caveats of cross-trial comparison, it seems that DCF induction chemotherapy does lead to relatively more toxicities.

It has been well-established that with increasing bony resection, the QOL of patients gets increasingly compromised.[95] However, with the addition of induction chemotherapy and associated toxicities, it would be important to objectively assess whether the strategy of induction

TABLE 1. Studies Evaluating the Role of Induction Chemotherapy for Mandibular Preservation in Patients With Locally Advanced Oral Cavity Carcinomas

Study	Trial Design	Patients Enrolled	Sample Size	Induction Chemotherapy Regimen	Response Rate to Induction Chemotherapy	Mandible Preservation Rate	Adjuvant Therapy	Oncological Outcomes
Licitra et al[98]	Phase III RCT comparing induction chemotherapy followed by surgery versus surgery alone	Untreated locally advanced resectable oral cavity squamous cell carcinoma; T2-T4 (>3 cm), N0-2	195	CF x 3 cycles: cisplatin 100 mg/m^2 + 5FU 1000 mg/m^2 as a 120-hour infusion once every 21 days	82% -CR: 28 (33%) -PR: 42 (49%)	21%; 95% CI, 7-34 (segmental mandibulectomy performed in 31% in the induction chemotherapy arm *v* 52% in the up-front surgery arm)	Adjuvant RT administered for high-risk patients. Criteria for high risk: -Positive surgical margins -Invasion of soft tissues of the face (cheek, chin) -Involvement of > 3 lymph nodes -Extracapsular tumor spread 32 (33%) in induction chemotherapy arm *v* 45 (46%) in the up-front surgery arm 13% difference; 95% CI, 0-27	5-yr EFS: induction chemotherapy arm 57% (95% CI, 46 to 67) *v* up-front surgery arm: 46% (95% CI, 36-57); *P* = .499 5-yr OS: Induction chemotherapy: 55% (95% CI, 45 to- 66), and up-front surgery: 55% (95% CI, 44 to 65); *P* = .767
Chaukar et al[13]	Phase II RCT comparing induction chemotherapy, followed by mandibular preservation surgery versus up-front surgery followed by adjuvant therapy	Untreated cT2-T4 and N0/N1, M0 oral squamous cell carcinoma, which required mandibular resection for paramandibular disease, with no clinicoradiologic bone erosion	68	DCF × three cycles: Docetaxel 75 mg/m^2 on day 1+ cisplatin 75 mg/m^2 on day 1 + 5FU 750 mg/m^2 on days 1-5; once every 21 days	38.2% CR: 1 (2.9%) PR: 12 (35.2%) SD: 16 (47.3%) PD: 2 (5.8%)	47% (95% CI, 31.49 to 63.24) Induction chemotherapy arm (n = 34): 14 (41.1%) underwent segmental mandibulectomy, 15 (44.1%) underwent marginal mandibulectomy, and 5 (14.8%) no surgery In up-front surgery arm, all 34 (100%) patients underwent segmental mandibulectomy	All patients in both arms received adjuvant RT with or without chemotherapy In induction chemotherapy arm: 26 (76.4%) received adjuvant CRT (weekly cisplatin 30 mg/m^2) and 3 (8.8%) received RT alone In up-front surgery arm, 16 (47%) received adjuvant CRT (weekly cisplatin 30 mg/m^2), 16 (47%) received adjuvant RT alone, and 2 (5.8%) were observed	Median DFS: Induction chemotherapy arm: 3.8 years (range, 0.04-9.38) and up-front surgery arm: 3.4 years (range, 0.13-8.74); HR 0.911 (95% CI, 0.516 to 1.607); *P* = .715 Median OS: Induction chemotherapy arm: 4.1 years (0.12-9.38) and up-front surgery arm: 3.4 years (range, 0.29-8.74); HR, 0.899 (95% CI, 0.510 to 1.587); *P* = .747

chemotherapy leads to an improvement in the QOL. Unfortunately, neither of the two studies reported the QOL of patients; hence, this remains an unanswered question.

Recommendation

In patients with locally advanced OSCC that would necessitate mandibulectomy, but no clinical and radiographic evidence of mandibular erosion, induction chemotherapy with three cycles of docetaxel + cisplatin + FU followed by an attempt at mandibular preservation surgery (possibly on the basis of the postinduction chemotherapy tumor volume) and adjuvant concurrent chemoradiotherapy may be a potential strategy for organ preservation, without compromising oncologic survival outcomes in carefully selected cases. Multidisciplinary discussion and patient-centered approach are the keys for selecting these potential cases.

ALTERNATIVE STRATEGIES TO CISPLATIN COMBINED WITH RADIOTHERAPY AS ADJUVANT TREATMENT

The established standard of care for patients with high-risk features (pENE and/or positive margins) is postoperative concurrent CRT with high-dose cisplatin at 100 mg/m^2 once every 3 weeks.[104] This strategy improves LRC, DFS, and OS. However, this comes with acute and long-term toxicities (eg, ototoxicity and nephrotoxicity). Besides, a substantial proportion of patients are platinum-ineligible or unfit. Hence, there have been multiple attempts to discover alternatives to high-dose cisplatin. Changing the schedule (ie, lowering the dose and administering cisplatin once a week) was the first strategy that was widely used in practice[105] and subsequently tested by several groups.[103,105-107] Noronha et al[108] found that once-weekly cisplatin at 30 mg/m^2 administered concurrently with adjuvant radiation was not noninferior to high-dose cisplatin once every 3 weeks and significantly lowered the LRC. Kiyota et al[107] increased the dose of once-weekly cisplatin to 40 mg/m^2 and found that this dose led to a noninferior OS as compared with high-dose cisplatin once every 3 weeks. However, the weekly cisplatin regimen also led to significant adverse events: 71.6% acute grade 3 and higher toxicities in the once-weekly cisplatin arm, which, although lower than the 84.6% grade 3 and higher toxicities in the once-every-3-weeks cisplatin arm, was certainly not insignificant. Thus, the search continued for alternatives to cisplatin.

Alternatives to Cisplatin in Platinum-Fit Patients

Reasons to seek out alternatives to cisplatin in patients who are fit include possible increased efficacy or decreased toxicity. A phase III RCT evaluating whether carboplatin added to radiation improved outcomes was stopped prematurely because of poor accrual; it showed no benefit in DFS from the addition of carboplatin to radiation. Although there are no studies that directly compared cetuximab with cisplatin as adjuvant CRT for OSCC, by extrapolating the data from the definitive setting, cetuximab does not seem to be an appropriate option for platinum-eligible patients. There have been attempts to escalate therapy with the addition of immune checkpoint inhibitors to standard definitive cisplatin-based CRT: avelumab in JAVELIN Head and Neck 100[109] and pembrolizumab in KEYNOTE-412,[110] both of which failed to improve outcomes. The GORTEC 2017-01 (REACH) study that evaluated the combination of immunotherapy with cetuximab as compared with cisplatin CRT (nonoperated) in locally advanced HNC (cisplatin-fit cohort) was recently stopped for futility.[111] In the adjuvant setting, the most promising data are for docetaxel + cetuximab.[112,113] Table 2 provides the details of studies that evaluated various alternatives to cisplatin CRT in the postoperative adjuvant setting. A noninferiority trial is currently assessing docetaxel to high-dose cisplatin concurrently with radiotherapy in both the adjuvant and definitive CRT settings.[116] Finally, the recently published OCAT study conducted on 900 patients with resected stage III/IV OSCC, and at least one poor prognostic feature on the histopathology (pENE, $\geq$2 involved regional lymph nodes, positive margin(s), extensive soft tissue and/or skin infiltration requiring major reconstruction, or perineural or lymphovascular invasion) reported that for the entire cohort, there was no difference in oncological outcomes (LRC, DFS, or OS) between the three arms: arm A—standard adjuvant radiotherapy alone (60 Gy/30 fractions, 5 days a week over 6 weeks); arm B—concurrent CRT with once-weekly cisplatin 30 mg/m^2 for six cycles with standard radiation (60 Gy/30 fractions, 5 days a week over 6 weeks); or arm C—accelerated radiation (60 Gy/30 fractions, 6 days a week over 5 weeks). The group of patients at the highest risk (ie, T3-4 N2-3 disease and pENE) was shown to have a significantly longer DFS and OS from both the addition of chemotherapy to standard radiation and the acceleration of radiation.[117]

Defining Cisplatin Ineligibility

Contraindications to cisplatin and to platinum in general may be absolute or relative. Based on the criteria established by Ahn et al,[118] absolute contraindications to cisplatin include an Eastern Cooperative Oncology Group (ECOG) PS score of 3 or 4, renal dysfunction (<50 mL/min), and grade 2 or higher organ dysfunction, including deafness, tinnitus, and neurologic dysfunction, hypersensitivity to platinum, pregnancy and lactation, and patients with HIV/AIDS with a CD4 count <200/μL. Relative contraindications to cisplatin, that is, conditions that skew the risk-benefit ratio of cisplatin, include an ECOG PS score of 2, age > 70 years, borderline organ dysfunction, calculated creatinine clearance of 50-60 mL/min, various comorbidities, lack of social support, previous cumulative platinum dose >200 mg/m^2, unintentional weight loss >20%, and the concurrent use of nephrotoxic drugs. In 2019, Szturz et al modified the criteria for cisplatin ineligibility and removed the age > 70 years criterion. In older persons, rather than using the chronological age and/or merely the PS of the patient to determine

TABLE 2. Randomized Studies in Patients With Locally Advanced Head and Neck Squamous Cell Carcinomas Evaluating Various Alternative Regimens to the Standard Cisplatin-Based Chemoradiotherapy

Study	Trial Design	Patients Included	Chemotherapy Regimens	Sample Size/No. of Patients With Oral Cavity Cancers (%)	Toxicities	Oncological Outcomes	Interpretation and Comments
Studies performed in cisplatin-eligible patients							
RTOG-0234 (Harari et al[113])	Phase II randomized study comparing the addition of cetuximab with cisplatin 30 mg/m^2 once per week or docetaxel 15 mg/m^2 once per week both concurrently with RT	Stage III-IV HNSCC postoperatively with high-risk pathologic features including positive margins, extracapsular extension, or >two positive lymph nodes	Cetuximab 400 mg IV loading dose, started 5-9 days pre-RT, then 250 mg/m^2 once weekly infusions × 6 (both arms) Cisplatin arm: cisplatin 30 mg/m^2 IV once weekly × 6 Docetaxel arm: 15 mg/m^2 IV once weekly × 6	N = 203; Oral cancers: 95 (46.8%)	Common grade 3 and higher toxicities (cisplatin + cetuximab *v* docetaxel + cetuximab): Mucositis: 55.7% *v* 53.8%, dysphagia: 38.1% *v* 36.8%, skin rash: 36.1% *v* 38.7%, hematologic toxicities: 27.8% *v* 14.2%	DFS in each arm was compared with the historic control of high-dose 3-weekly cisplatin in the RTOG 9501 study: Cisplatin + cetuximab arm: 2-year DFS: 57%; HR, 0.76; 95% CI, 0.54 to 1.06; *P* = .05 Docetaxel + cetuximab: 66%; HR, 0.69; 95% CI, 0.50 to 0.96; *P* = .01; 2-year OS: Cisplatin arm: 69% Docetaxel arm: 79%	Docetaxel + cetuximab as postoperative CRT led to an absolute improvement in 2-year DFS of 11.1% as compared with the historical control (RTOG 9501) and seems to be a promising regimen
Argiris et al[114]	Phase III randomized study comparing carboplatin + RT with RT alone in the postoperative setting for high-risk HNSCC	Stage III/IV HNSCC with macroscopic resection, with at least one high-risk pathologic feature: ≥three lymph nodes, extracapsular extension, perineural or angiolymphatic invasion, or positive margins (0.5 mm or less)	Carboplatin 100 mg/m^2 IV once weekly × 6	N = 72; Oral cancers: 25 (34.7%)	Carboplatin did not lead to a significant increase in toxicities; No grade 4 toxicities Grade 3 toxicities: 18% in RT alone arm, *v* 36% in carboplatin + RT arm; *P* = .17	2-year DFS (primary end point): RT alone, 58% (95% CI, 39 to 76) *v* carboplatin + RT-71% (95% CI, 56 to 88); HR, 0.82, *P* = .6 2-year OS: RT alone, 51% *v* carboplatin + RT-74%; *P* = .04	Carboplatin when added to postoperative RT did not prolong 2-year DFS (13% absolute improvement in 2-year DFS from the addition of carboplatin but statistically negative); study was terminated early because of poor accrual

Study	Trial Design	Patients Included	Chemotherapy Regimens	Sample Size/No. of Patients With Oral Cavity Cancers (%)	Toxicities	Oncological Outcomes	Interpretation and Comments
Studies performed in cisplatin-ineligible patients							
DHANUSH (Patil et al[115])	Phase II/III randomized trial comparing docetaxel with cisplatin concurrently with RT in cisplatin-unfit patients	HNSCC, arising in oral cavity, oropharynx, hypopharynx, larynx, planned for radical RT (both definitive and adjuvant) who were deemed platinum-ineligible	Docetaxel 15 mg/m^2 IV once weekly × maximum seven cycles	N = 356; Oral cavity cancers: 133 (37.4%) Postoperative setting: 139 (39%)	Grade 3 and higher toxicities: RT alone, 102 (58%) *v* docetaxel + RT-146 (81.6%), $P = .001$; Common grade 3 or higher toxicities (RT *v* docetaxel + RT): Mucositis, 22% *v* 49.7%; $P < .001$; Odynophagia, 33.5% *v* 52.5%, $P < .001$; Dysphagia, 33% *v* 49.7%; $P = .002$; Dermatitis, 8.5% *v* 15.1%; $P = .07$; Hyponatremia, 19.3% *v* 30.2%; $P = .02$	2-year DFS (primary end point for the phase II): RT alone, 30.3% (95% CI, 23.6 to 37.4) *v* docetaxel: 42% (95% CI, 34.6 to 49.2); HR, 0.673 (95% CI, 0.521 to 0.868; $P = .002$); Median locoregional failure-free survival: RT alone, 5.9 months (95% CI, 4.9 to 7.5) *v* docetaxel + RT-12.4 months (95% CI, 8.6 to 23.5); HR, 0.661 (95% CI, 0.512 to 0.854; $P = .002$); 2-year OS: RT alone, 41.7% (95% CI, 34.1 to 49.1) *v* docetaxel + RT-50.8% (95% CI, 43.1 to 58.1); HR, 0.747 (95% CI, 0.569 to 0.980; $P = .035$)	Docetaxel when added to RT (both definitive and adjuvant) in cisplatin-ineligible patients significantly prolonged DFS and OS

Abbreviations: CRT, chemoradiation; DFS, disease-free survival; HNSCC, head and neck squamous cell carcinoma; HR, hazard ratio; IV, intravenous; OS, overall survival; RT, radiation.

cisplatin suitability, a geriatric assessment is appropriate to evaluate for frailty and various vulnerabilities.[119,120] Szturz et al also recommended that grade 2 hearing impairment should be a relative rather than an absolute contraindication.

Alternatives to Cisplatin in Platinum-Unfit Patients

Extrapolating the data from the cisplatin-eligible setting, carboplatin is likely to be ineffective and should not be used, although it has been a relatively popular choice in the past for cisplatin-ineligible patients. Various alternative chemotherapeutic options such as paclitaxel + carboplatin have been described in case series/retrospective cohorts.[121] Although there is no convincing evidence that cetuximab is used in the postoperative setting on patients who are cisplatin-ineligible, by extrapolation, on the basis of the trial of Bonner et al[122] (definitive CRT, nonoral cavity subsites).

The results of the DHANUSH study proved that docetaxel when added to radiation in patients who were cisplatin-ineligible (defined as per Ahn's criteria) significantly prolonged both DFS and OS.[115,118] The enrollment criteria were broad: locally advanced HNSCC arising in the oral cavity, oropharynx, hypopharynx, and larynx and carcinoma of unknown primary, warranting radiation in the definitive or adjuvant settings. There was no significant interaction between the addition of docetaxel and the treatment settings, that is, docetaxel was effective in both the definitive and adjuvant settings. There was a significant increase in toxicities from the addition of docetaxel; however, the QOL was maintained. There were 160 patients (44.9%) with ECOG PS 2 and 58 (16.3%) who were older than 70 years; thus, the regimen is suitable for a relatively frail population.

Finally, this is an area of active research, with a slew of newer molecules undergoing testing. One such promising drug is xevinapant, an antagonist of inhibitor of apoptosis proteins.[123] The XRAY VISION study will evaluate the efficacy of xevinapant in the postoperative setting in cisplatin-ineligible patients.[124]

Recommendation

In cisplatin-eligible patients, the standard of care for OSCC with high-risk features is high-dose cisplatin 100 mg/m^2 once every 3 weeks or lower-dose cisplatin 40 mg/m^2 once weekly, which should be added concurrently to radiotherapy. In cisplatin-ineligible patients, docetaxel 15 mg/m^2 once weekly with PORT is supported by the best evidence. Other possible options include concurrent cetuximab, carboplatin/5FU, carboplatin/paclitaxel, or the use of accelerated radiation.

Management of Advanced Thyroid Cancer: Overview, Advances, and Opportunities

Sarimar Agosto Salgado, MD[1]; Erin Rachel Kaye, MD[2]; Zoukaa Sargi, MD, MPH[3]; Christine H. Chung, MD[1]; and Maria Papaleontiou, MD[4]

overview

Thyroid cancer is the most common endocrine malignancy with almost one million people living with thyroid cancer in the United States. Although early-stage well-differentiated thyroid cancers account for the majority of thyroid cancers on diagnosis and have excellent survival rates, the incidence of advanced-stage disease has increased over the past few years and confers poorer prognosis. Until recently, patients with advanced thyroid cancer had limited therapeutic options. However, the landscape of thyroid cancer treatment has dramatically changed in the past decade with the current availability of several novel effective therapeutic options, leading to significant advances and improved patient outcomes in the management of advanced disease. In this review, we summarize the current status of advanced thyroid cancer treatment options and discuss recent advances made in targeted therapies that have proven promising to clinically benefit patients with advanced thyroid cancer.

Author affiliations and support information (if applicable) appear at the end of this article.

Accepted on April 5, 2023 and published at ascopubs.org on May 15, 2023: DOI https://doi.org/10.1200/EDBK_389708

INTRODUCTION

Thyroid cancer is the most common endocrine malignancy with the prevalence in the United States currently exceeding 900,000 cases.[1] Overall, the majority of thyroid cancers detected are early-stage well-differentiated thyroid cancers (DTCs) that have an excellent prognosis[1]; however, some evidence shows that the incidence of advanced thyroid cancers has increased in recent years.[2] In 2022, 2,230 patients died of thyroid cancer in the United States.[1]

Follicular-derived thyroid cancers include papillary thyroid cancer, follicular thyroid cancer, Hürthle cell cancer, poorly DTC, and undifferentiated (anaplastic) thyroid cancer (ATC). Although surgery and radioactive iodine (RAI) are the standard of care for DTCs often leading to cure, patients with radioactive-iodine refractory (RAIR) disease, DTCs, and ATCs confer poorer prognosis and pose significant challenges for treating clinicians. Medullary thyroid cancer (MTC) arises from parafollicular or C cells and accounts for fewer than 5% of thyroid cancer diagnoses but approximately 13% of thyroid cancer deaths.[3] Overall, approximately 20% of cases are familial secondary to a germline rearranged during transfection (*RET*) mutation while the remaining cases are sporadic.[4] Patients with MTC who present with regional lymph node metastases and/or distant metastases are less likely to be cured of their disease.[5]

This review focuses on the current status of advanced thyroid cancer treatment options, summarizing the role of surgery in advanced thyroid cancer management, challenges in the management of RAIR thyroid cancer, and advances in systemic therapies, particularly progress pertaining to targeted therapies.

DEFINITION OF ADVANCED THYROID CANCER

Advanced thyroid cancer is a term used to describe aggressive tumors; however, there is significant variability among specialties. Surgeons refer to unresectable tumors as advanced thyroid cancers, endocrinologists to describe RAIR tumors, and oncologists when there are distant metastases.[6] A recent consensus statement by the American Head and Neck Society (AHNS) Endocrine Surgery Section and International Thyroid Oncology Group defined advanced thyroid cancer according to four categories. The *structural/surgical* category encompasses the following: (1) bulky, invasive, or inoperative locoregional disease; (2) recurrence; (3) distant metastases; (4) gross residual neck disease without option for reoperation; (5) rapid progression on imaging; and (6) imminent threat posed by tumor burden. Tumors refractory to RAI, unresponsive to thyroid-stimulating hormone (TSH) suppression, and rapid calcitonin, carcinoembryonic antigen, or thyroglobulin doubling times constitute the *biochemical* category. The *histologic/molecular* category includes findings such as poorly differentiated or other aggressive histology components, high Ki67 index, high mitotic count or tumor necrosis, and all anaplastic thyroid carcinoma. Finally, tumors can be categorized as advanced thyroid cancer at the discretion of the treating physician if there are features that portend aggressive tumor behavior (*clinician prero*gative).

PRACTICAL APPLICATIONS

- Surgical management of advanced thyroid cancer is challenging and should evolve from multidisciplinary discussion integrating individual disease characteristics, expected surgical morbidity, and patient preferences.
- Common clinical scenarios suggestive of radioactive iodine (RAI) refractory thyroid cancer include a negative diagnostic RAI uptake whole-body scan, loss of RAI uptake on post-therapy RAI scan, presence of RAI in some tissues but not others, and metastatic disease progression despite ability to concentrate RAI, including a cumulative activity of >600 mCi.
- An improved understanding of thyroid cancer pathogenesis has led to a remarkable change in the landscape of available systemic targeted therapies for patients with advanced and refractory disease in the past several years.
- Treatment decisions regarding use of targeted therapies for advanced thyroid cancer should be made judiciously by a multidisciplinary team while weighing risks versus benefits and undertaking close surveillance for disease progression and adverse events.

ROLE OF SURGERY IN ADVANCED THYROID CANCER

DTC

The 2015 American Thyroid Association (ATA) guidelines established protocols for surgically managing tumors on the basis of size, stage, and aggressive features.[7] The guidelines provide guidance regarding surgical indications and extent of surgery (lobectomy *v* total thyroidectomy). There has been a shift toward lobectomy in certain cases, as detailed below.

Preoperative workup in patients with thyroid cancer includes imaging and thyroid function tests. Ultrasound is the recommended initial imaging modality and should include the thyroid, central compartment, and bilateral lateral neck nodes.[7] Additional imaging, that is, computed tomography (CT) and magnetic resonance imaging (MRI) with intravenous contrast, is recommended in patients with advanced thyroid cancer, suspicion for local invasion, and multiple or bulky lymphadenopathy. Chest CT should be considered if there is concern for low mediastinal nodes or pulmonary metastasis. Positron emission tomography (PET) may be used in recurrent cases or for surveillance.[8] In cases of advanced disease when invasion is suspected, additional preoperative workup including larynx evaluation, swallow function, and dedicated imaging with CT of the chest (trachea) and MRI (esophagus) is recommended.[9]

According to the ATA guidelines, patients with DTC are subdivided into three categories with treatment implications[7]:

1. Thyroid cancer >4 cm, gross extrathyroidal extension (ETE; clinical T4), nodal disease (clinical N1), or distant metastasis
2. Thyroid cancer >1 cm and <4 cm without ETE and without nodal disease or metastasis
3. Thyroid cancer <1 cm without ETE and without nodal disease

For group 1, total thyroidectomy is the recommended treatment. For patients in group 2, either option of lobectomy or total thyroidectomy is acceptable. The decision-making process regarding the extent of surgical resection in these patients involves a cohesive discussion between the treatment team and the patient. If RAI is planned or likely to be recommended, total thyroidectomy would be indicated. Finally, for patients in group 3, watchful waiting with surveillance may be an option in cases of low-risk differentiated tumors; if surgery is preferred, thyroid lobectomy is recommended unless there is an indication to remove the contralateral lobe or a history of previous head and neck radiation or familial thyroid carcinoma.[7,10]

The ATA guidelines also incorporate indications for nodal dissection. With clinically evident central compartment and/or lateral neck disease, dissection is recommended at the time of initial surgery. Central compartment lymph node dissection, or level VI, includes pretracheal and paratracheal nodes. Lateral neck dissection typically incorporates level II-IV nodal levels, extending from the skull base superiorly to the clavicle inferiorly and from the strap muscles medially to the posterior border of the sternocleidomastoid muscle laterally. Nodal dissection of an additional level may be incorporated if there is clinically evident nodal disease. Prophylactic central compartment dissection can be considered in patients with advanced papillary carcinoma (T3 or T4), clinically involved lateral nodes, or if the nodal tissue may guide adjuvant treatment.[7]

In regard to management of invasive DTC, which occurs in up to 15% of patients, the AHNS published a series of consensus statements in 2014.[9] These consensus statements can be used to guide preoperative workup and intraoperative management. The recurrent laryngeal nerve (RLN) is involved in 33%-61% of patients with invasive cancer. Fiberoptic laryngoscopy is the preferred method of laryngeal evaluation, particularly when voice is abnormal, if history of thyroid surgery, or if ETE is suspected. Management of the RLN during surgery varies according to preoperative function, degree of invasion, and status of the contralateral nerve and has important functional

implications for voice, breathing, and swallow. Although intraoperative RLN monitoring is commonly used for evaluation of nerve status, the nerve should still be identified intraoperatively.[7,11,12] Postoperative unilateral dysfunction is often evident if voice changes occur and may lead to aspiration, whereas bilateral dysfunction typically presents with shortness of breath and stridor. Preservation of the parathyroid glands should be attempted with dissection along the thyroid capsule to avoid inadvertent injury to their vascular supply. Intraoperatively, the thyroid specimen should be carefully examined after removal for any parathyroid tissue. If identified, the parathyroid should be reimplanted into nearby muscle, and postoperative calcium and parathyroid hormone levels should be monitored.[7]

Additional structures including the trachea and larynx may be abutted or directly invaded in patients with advanced DTC. If invasion is suspected, direct laryngoscopy and bronchoscopy are performed. The extent of invasion helps to guide the recommended intraoperative decision making, for example, whether to perform a tracheal shave versus a circumferential tracheal resection or partial versus total laryngectomy.[9] Because esophageal invasion usually involves only the muscularis layer, extent of invasion may not be seen on esophagoscopy. Similar to the larynx and trachea, esophageal resection may be limited to the outer layers or involve composite resection if intraluminal tumor is present.[9] Although rare, in cases of suspected major vascular invasion by tumor, CT or magnetic resonance angiogram is performed preoperatively. If the carotid artery is involved, balloon occlusion testing and potential carotid sacrifice may be considered in select cases of differentiated, locally advanced cancers.[9]

It is important to note that nearly one-quarter of patients with invasive cancer die from airway obstruction secondary to tracheal invasion and 28% from respiratory failure secondary to lung involvement.[13] Patients with locally invasive cancer who are candidates for surgical resection and achieve gross total resection have good outcomes, with one study reporting >90% 5-year disease-free survival.[14] Tumors invading the prevertebral fascia or encasing the carotid artery are classified as unresectable; however, there are instances when near total gross resection may be indicated for palliation in well-differentiated tumors with overall good outcome.[15] In addition, palliation with tracheostomy may be recommended in patients where airway obstruction from tumor is imminent or when planned for nonsurgical therapy.[16] Finally, as more targeted therapies are being selectively used, some patients who would not have been good candidates for surgery may now be considered for surgical treatment either for local disease control or for palliation. The nuances stemming from having received neoadjuvant treatment and the implications on surgery remain to be studied.

Finally, in 2016, the AHNS published a consensus statement recommending revision surgery for tumor and nodal recurrence, if feasible. In revision surgery, the primary goal is to remove recurrent cancer in the thyroid or nodal tissue, remove remaining thyroid tissue, and perform nodal dissection in regions suspected to have microscopic disease.[17]

Medullary Thyroid Carcinoma

Total thyroidectomy and central neck dissection (level VI), with dissection of lymph nodes in the lateral compartments (levels II-V) depending on calcitonin levels and ultrasound findings, is a standard treatment for patients with sporadic or hereditary MTC.[18,19] When preoperative imaging is positive in the ipsilateral lateral neck compartment but negative in the contralateral neck compartment, contralateral neck dissection should be considered if the basal serum calcitonin level is >200 pg/mL.[18]

Anaplastic Thyroid Carcinoma

Surgical options must be carefully evaluated in patients with ATC while balancing risks and benefits with goals of care. The primary goal for resectable tumors (stages IVA and IVB) is an aggressive approach with complete resection, followed by definitive chemoradiation. In stage IVC ATC, the limited benefit from surgery must be carefully weighed against other palliative approaches, such as radiation and systemic therapy.[20]

RAIR-DTC

After thyroidectomy, RAI remains the most frequently used adjuvant therapy for follicular-derived thyroid cancers, with the main goals to improve disease-specific survival, reduce recurrence rates, and improve progression-free survival (PFS).[7] However, several patients with advanced DTC are radioactive-iodine resistant/refractory. According to the 2015 ATA guidelines, DTCs are considered refractory to RAI when (1) they do not concentrate RAI at the time of initial treatment, such as in patients with structurally evident disease and a negative RAI uptake whole-body scan, suggesting that RAI treatment would provide no clinical benefit; (2) they lose their ability to concentrate RAI in the setting of previous RAI uptake, often occurring in patients with multiple large metastases; (3) concentrate RAI in some tissues but not others, evident by comparing findings from a RAI whole-body scan with those from a ^{18}FDG-PET scan; or (4) there is metastatic disease progression despite ability to concentrate RAI.[7] However, the exact definition of RAIR-DTC is still controversial, and different definitions have been proposed by different societies. A recent consortium of experts from the ATA, the European Association of Nuclear Medicine, the Society of Nuclear Medicine and Molecular Imaging, and the European Thyroid Association noted that no current definition, classification, criterion, or clinical scenario is an absolute indicator that a patient has RAIR-

DTC.[21] The common clinical scenarios suggesting that a patient may have RAIR-DTC derived from this consortium are outlined in Table 1 and provide a framework addressing important management issues in patients with RAIR-DTC. Importantly, factors such as the amount of RAI uptake on post-therapy whole-body scans compared with the total RAI dose the patient received, tolerability of side effects, and tumor response to previous RAI treatments should be considered to optimize therapy in these patients.

Patients with inoperable and/or metastatic RAIR-DTC have a worse overall prognosis than those who have RAI-sensitive follicular-derived thyroid cancers.[21-23] Before the routine availability of targeted therapies, studies showed that patients with RAIR-DTC had median 5-year disease-specific survival rates of 60%-70%, and those with metastatic RAIR-DTC had the worse outcomes with a median 10-year survival rate of 10%.[23,24] The significance of identifying patients who may harbor RAIR disease lies with the need for early intervention in these patients to improve disease-free progression and survival, with molecular testing and mutational mapping having emerged as adjuncts to imaging and pathology of identification of more aggressive disease.

Many patients with RAIR-DTC have slow-growing, low-volume disease. For patients with asymptomatic RAIR-DTC which may persist for years, low tumor burden or minimal progression over time, watchful waiting with TSH suppression, and periodic imaging can be used.[25-27] In patients with locoregional recurrence, surgical intervention is usually used as the therapeutic approach of choice, with external-beam radiation therapy used in combination with surgery in select cases.[25] Typically, symptomatic patients with distant metastases to the lungs and/or bone are often offered local therapies before consideration of systemic treatments.[28]

SYSTEMIC THERAPY IN ADVANCED THYROID CANCER

The decision to initiate systemic therapy in thyroid cancer is an area in endocrine oncology where significant clinical practice variability exists. The specific histopathological variables play a role in the timing of antineoplastic treatment. In general, the sole increase of tumor markers is not decisive in starting systemic therapy for thyroid cancer. Patients with metastatic RAIR-DTC and MTC with asymptomatic disease and small tumors with slow indolent progression are amenable to close active surveillance with serial imaging.[29] Specifically, for RAIR-DTC and MTC, targeted therapy is recommended for (1) rapidly progressive tumors not amenable or failure to alternative localized therapies, (2) symptomatic disease, or (3) tumors in a threatening location.[7,30]

The evolving availability of different molecular testing modalities has allowed the incorporation of precision oncology for prognostic and therapeutic purposes in advanced thyroid cancer and is consistent with current National Comprehensive Cancer Network guidelines.[31] Given the potential for druggable targets, the preferred somatic testing approach is next-generation sequencing (NGS) in contrast to single-gene tests.[6] All ATC tumors should undergo molecular testing. However, immunohistochemistry (IHC) evaluation for BRAF V600E should also be incorporated into the initial assessment of ATC while awaiting NGS results; rapid BRAF V600E IHC–positive results can lead to early therapeutic interventions with dabrafenib and trametinib.

TABLE 1. Common Clinical Scenarios Suggestive of RAIR-DTC

Clinical Scenario	Considerations
No RAI uptake on diagnostic ^{131}I scan	Adequate low-iodine diet and TSH stimulation before scan High-resolution imaging with SPECT/CT scan provides more functional detail than planar imaging
No RAI uptake on a post-therapy ^{131}I scan (performed several days after therapy)	Post-therapy ^{131}I scans may miss up to 12% of DTC metastases that have RAI uptake
RAI uptake is only present in some but not other tumor tissues	Can treat RAI-avid tumor tissues with ^{131}I and use local treatment modalities for non–RAI-avid tissues
Progression of DTC metastases despite ^{131}I uptake	Metric used for successful response to previous ^{131}I therapy, duration of response, metric used to determine progression of disease post-^{131}I therapy, amount of ^{131}I activity previously administered, potential for administering higher ^{131}I activity, side effects, and patient preferences should be considered when deciding to pursue additional ^{131}I administrations
Progression of DTC metastases despite cumulative ^{131}I activity of >600 mCi	Increased likelihood of DTC becoming RAIR with increased cumulative ^{131}I activity and number of doses Response to previous treatments, duration of response, individual ^{131}I activity administered in each previous treatment, side effects, and patient preferences should be considered when deciding to pursue additional ^{131}I administrations

Abbreviations: DTC, differentiated thyroid cancer; mCi, millicuries; RAI, radioactive iodine; RAIR, radioactive-iodine refractory; SPECT/CT, single-photon emission computed tomography with computed tomography; TSH, thyroid-stimulating hormone.

For the remaining thyroid cancer variants, molecular testing should be considered in the setting of RAIR-DTC, locally invasive or unresectable tumors, distant metastatic disease, and aggressive histological features and on the basis of the clinician's judgment.[6] Available systemic targeted therapies for advanced thyroid cancers and their mechanism of action are outlined in Table 2 and Figure 1.

DTC

Initial oral antineoplastic regimens for advanced thyroid cancers consisted of multikinase inhibitors (MKIs). The DECISION study, a phase III multicenter randomized, double-blind clinical trial, evaluated the utilization of sorafenib 400 mg twice daily versus placebo. Study treatment in this trial continued until radiographically documented disease progression, unacceptable toxicity, noncompliance or withdrawal of consent. Sorafenib resulted in a meaningful improvement in PFS of 10.8 versus 5.8 months in the placebo cohort (hazard ratio [HR], 0.59; 95% CI, 0.45 to 0.76; $P < .0001$). The overall response rate (ORR) was 12.2% versus 0.5% in favor of sorafenib.[32] Adverse events occurred in most patients (98.6%) treated with this MKI, classified predominantly as grade 1-2. Common noted side effects included hand-foot skin reaction (76.3%), diarrhea (68.6%), alopecia (67.1%), rash (50.2%), fatigue (49.8%), weight loss (46.9%), hypertension (40.6%), anorexia (31.9%), and mucositis (23.2%), among others.[32]

Furthermore, lenvatinib, an MKI aiming at vascular epithelial growth factor receptor (VEGFR), fibroblast growth factor receptors, RET, KIT, and platelet-derived growth factor receptor α, has shown substantial responses in advanced thyroid cancer. In the SELECT trial, the lenvatinib-treated cohort attained a PFS of 18.3 months compared with 3.6 months in the placebo group (HR, 0.21; 99% CI, 0.14 to 0.31; $P < .001$).[33] In patients pretreated with another MKI, lenvatinib, the PFS was 15.1 months. The ORR is 64.8% in the oral antineoplastic cohort; the majority were partial responses (63.2%) by RECIST 1.1. In addition, lenvatinib has demonstrated a benefit in the overall survival of patients older than 65 years. Frequently noted adverse events included hypertension (67.8%), diarrhea (59.4%), fatigue (59%), decreased appetite (50.2%), weight loss (46.4%), nausea (41%), stomatitis (35.6%), palmar-plantar erythrodysesthesia syndrome (31.8%), proteinuria (31%),

TABLE 2. Summary of Systemic Targeted Therapies in Advanced Thyroid Cancer

Targeted Therapy	Tumor Target	Response	Common Side Effects
Multikinase inhibitors-DTC			
Sorafenib	VEGFR, PDGFR, RET	PFS, 10.8 months ORR, 12%	Hand-foot, diarrhea, alopecia, rash, fatigue, weight loss, HTN
Lenvatinib	VEGFR, PDGFR, RET, FGFR	PFS, 18.3 months ORR, 64.8%	HTN, diarrhea, fatigue, decreased appetite, weight loss, nausea
Multikinase inhibitors-MTC			
Vandetanib	RET, VEGFR, EGFR	ORR, 45%	Diarrhea, rash, HTN, nausea, headache
Cabozantinib	RET, VEGFR, c-MET		Diarrhea, HTN, hand-foot syndrome
BRAF/MEK inhibitors			
Dabrafenib and trametinib	BRAF V600E	DTC: dabrafenib alone ORR, 42% *v* dabrafenib plus trametinib ORR, 48% ATC: ORR, 61%	Fever, fatigue, nausea, chills, skin toxicities (rash, skin cancers)
RET inhibitors			
Selpercatinib	RET	*RET* fusion-TC (previously treated) ORR, 79% *RET*-mutant MTC (no previous treatment) ORR, 73% *RET*-mutant MTC (previously treated) ORR, 69%	Dry mouth, gastrointestinal side effects, elevated liver enzymes, QT prolongation
Pralsetinib	RET	*RET* fusion-TC ORR, 85.7% *RET*-mutant MTC (no previous treatment) ORR, 71% *RET*-mutant MTC (previously treated) ORR, 60%	Dry mouth, gastrointestinal side effects, elevated liver enzymes, QT prolongation
NTRK inhibitors			
Larotrectinib	NTRK	*NTRK* fusion-TC ORR, 71%	Myalgia, fatigue, elevated liver enzymes, edema, gastrointestinal side effects

Abbreviations: ATC, anaplastic thyroid cancer; DTC, differentiated thyroid cancer; EGFR, epidermal growth factor receptor; FGFR, fibroblast growth factor; HTN, hypertension; MTC, medullary thyroid cancer; ORR, overall response rate; PDGFR, platelet-derived growth factor α; PFS, progression-free survival; RET, rearranged during transfection; TC, thyroid cancer; VEGFR, vascular epithelial growth factor receptor.

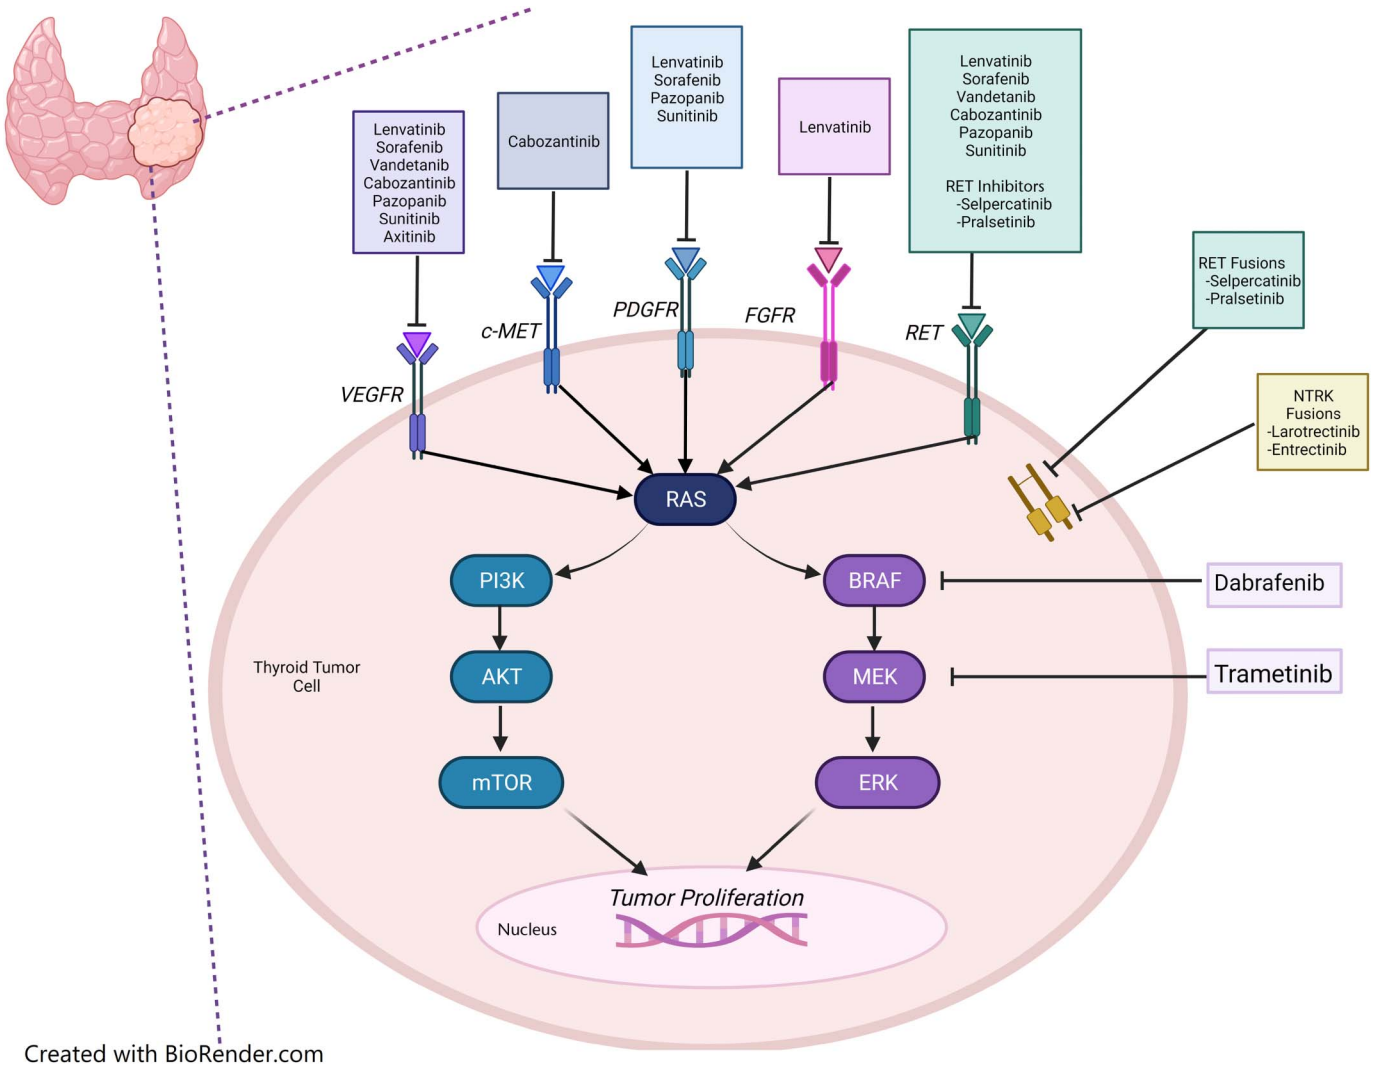

FIG 1. Available systemic targeted therapies for advanced thyroid cancer and mechanisms of action. ERK, extracellular-regulated kinase; FGFR, fibroblast growth factor; mTOR, mammalian target of rapamycin; PDGFR, platelet-derived growth factor α; PI3K, phosphatidylinositol 3-kinase; RET, rearranged during transfection; VEGFR, vascular epithelial growth factor receptor.

vomiting (28.4%), headache (27.6%), and dysphonia (24.1%), among others.[33]

Both sorafenib and lenvatinib are Food and Drug Administration (FDA)–approved therapies in the United States for advanced RAIR-DTC. Given the development of resistance mechanisms resulting in progression, many patients with advanced thyroid cancer require an eventual change in treatment. Recently, cabozantinib has received FDA approval as second-line therapy for RAIR-DTC on the basis of COSMIC-311 study results. In this trial, which enrolled patients after progression on anti-VEGFR therapy, cabozantinib resulted in a PFS of 11 months over 1.9 months in placebo with an ORR of 11%.[34] The best overall responses included 11% partial responses, 69% stable disease, and a confirmed complete response (1%).[34] Adverse event profile was similar to previous discussed antiangiogenic MKIs, including any-grade diarrhea (62%), palmar-plantar erythrodysesthesia (47%), and hypertension (32%).[34] Smaller studies have explored the utilization of additional MKIs in RAIR-DTC, including pazopanib, sunitinib, vandetanib, and axitinib.[35-38]

Although MKIs described above are used without any biomarker selection, there are several inhibitors that are approved only in presence of specific gene alterations. For *BRAF V600E*–altered RAIR-DTC, the utilization of BRAF and MEK inhibitors has been studied, given the success of these therapies in other solid tumors. Recently, a phase II open-label multicenter clinical study explored the implementation of BRAF inhibitor dabrafenib alone or in combination with a MEK inhibitor.[39] Using a modified

RECIST including minor responses (decreased tumor by 20%-29%), partial and complete responses, the ORR-modified RECIST was 42% for dabrafenib monotherapy versus 48% dabrafenib with trametinib ($P = .67$). Periodic dermatological assessments are recommended as skin toxicities can occur, especially if treated with dabrafenib monotherapy (65%). Pyrexia was present in both cohorts in more than 50% of patients. In addition, BRAF inhibitor alone was commonly associated with hyperglycemia, whereas the BRAF/MEK inhibitor had a frequency of 52% for fatigue, nausea, and chills.[39]

Highly selective RET inhibitors, including selpercatinib and pralsetinib, have been approved for metastatic *RET*-mutant MTC and *RET* fusion–positive progressive RAIR-DTC. In previously treated *RET* fusion–positive thyroid cancer, the objective response was 79% with a PFS of 20.1 months. Best response distribution by RECIST 1.1 was 5% complete responses, 74% partial responses, and 21% stable disease.[40] In this group of patients with thyroid cancer, who were on pralsetinib, the ORR was 85.7% with a PFS of 19.4 months.[41] Both antineoplastic agents had dose reduction requirements in <45% of patients, which is a reflection that the majority of adverse events were minor in severity (grade 1-2). Common adverse events of RET inhibitors include dry mouth, gastrointestinal side effects, elevated transaminases, and QT prolongation. With selpercatinib, grade 3 events occurred in a minority of patients including hypertension (12%) and high liver enzymes (17%), and in <5% headache, diarrhea, QT prolongation, and weight gain.[40] Cytopenias are more frequently developed with pralsetinib; grade 3 side effects noted (>10%) included hypertension, neutropenia, lymphopenia, and anemia. Severe rare side effects may happen, including pneumonitis in a minority of patients (4%) or hypersensitivity reactions.[41,42] *NTRK* gene rearrangements have been reported in up to 6.7% of papillary thyroid cancers; in pediatric patients, the frequency of *NTRK* fusions is higher.[43] Grouped data from several phase I/II trials revealed a 71% ORR for larotrectinib, a NTRK inhibitor.[44] Common side effects included myalgia, fatigue, nausea, transaminitis, edema, and gastrointestinal symptoms; nevertheless, toxicities were low grade and <10% dose reductions.[44]

The profound responses and toxicity profile of the gene alteration–specific antineoplastic agents such as the RET, NTRK, and ALK inhibitors highlight the importance of ensuring that patients with advanced thyroid cancer undergo comprehensive molecular testing, including comprehensive evaluation of mutations and gene rearrangements. In addition, several clinical trials and case reports demonstrate restoration of iodine uptake in tumors, an approach known as redifferentiation, after a course of the gene alteration–specific inhibitors targeting BRAF, MEK, RET, or NTRK. The advantages include the possibility of discontinuation of targeted therapy after an additional RAI treatment, resulting in tumor control. Nevertheless, further studies are warranted to identify the best responders to ensure the appropriate selection of candidates and ideal implementation time on the disease course.[45-48]

Medullary Thyroid Carcinoma

Vandetanib, an MKI-targeting RET, VEGFR, and epidermal growth factor receptor, was, to our knowlege, the first FDA-approved targeted therapy for MTC.[49-51] After safety and tolerability data from phase II trials, the phase III ZETA trial demonstrated improvement in the PFS compared with placebo; however, this trial did not require progression at the time of enrollment. Cabozantinib-treated patients had an improvement in PFS of 11 months versus 4 months in placebo.[52]

Both RET inhibitors, selpercatinib and pralsetinib, induced sustained responses in *RET*-mutant MTC. *RET*-mutant MTC cases without previous targeted therapies treated with selpercatinib had an objective response of 73% and 69% for pretreated patients.[40] Pralsetinib resulted in an ORR of 71% for *RET*-mutant, treatment-naïve MTC versus 60% in the cohort previously treated by vandetanib, cabozantinib, or both TKIs.[41] As expected with targeted therapies, the predominant responses were partial responses, 67% and 58% in the previously mentioned cohorts, respectively.[41] Neoadjuvant RET inhibitor treatment has shown promise to facilitate successful resection of thyroid cancers; this novel utilization of targeted therapy is currently studied in clinical trials.[53,54]

Anaplastic Thyroid Carcinoma

ATC, as a stage IV highly lethal malignancy, benefits from expedited comprehensive evaluation, airway assessment, and molecular testing (BRAF V600E and NGS). For resectable tumors (stage IVA-IVB), surgical resection is followed by definitive chemoradiation. Between 20% and 50% of ATC tumors are driven by *BRAF V600E* mutation, allowing for combination dabrafenib and trametinib therapy in a neoadjuvant approach for stage IVB unresectable tumors or as up-front long-term therapy for stage IVC disease.[20] Combination BRAF/MEK inhibitor in *BRAF*-altered ATC has demonstrated an ORR of 61%, including complete responses.[55] Targeted therapies have improved overall survival in ATC.[56] RET or NTRK inhibitors may be used in the management of ATC tumors with the respective identified fusion drivers. In addition, immunotherapy, particularly in combination therapies, whether along BRAF/MEK inhibitor or antiangiogenics, has provided further therapeutic pathways for patients with ATC.[57-59] Consideration for enrollment in ongoing clinical trials is recommended given the rarity and aggressiveness of this tumor.

CONCLUSION

Management of advanced thyroid cancer requires a multidisciplinary approach to optimize patient outcomes and provide access to the latest cutting-edge therapies. There has been significant progress in understanding the genetic landscape and molecular basis of thyroid cancer, leading to the development of novel targeted therapies for advanced disease. These advances have revolutionized the management of patients with advanced thyroid cancer leading to improved PFS; however, questions still remain in regard to optimal timing of systemic treatment initiation for advanced thyroid cancer and relevant variables that inform decision making. Future studies on redifferentiation and neoadjuvant therapy in the presence of bulky neck disease, immunotherapy, and development of other gene alteration–specific therapies will hopefully further advance the field leading to thyroid cancer cure.

Personalizing Surveillance in Head and Neck Cancer

Glenn J. Hanna, MD[1]; Nirali Patel, MD[2]; Sara G. Tedla, MD[3]; Kristen L. Baugnon, MD[3]; Ashley Aiken, MD[3]; and Nishant Agrawal, MD[2]

overview

Head and neck squamous cell carcinoma (HNSCC) encompasses a spectrum of heterogeneous diseases originating in the oral cavity, pharynx, and larynx. Within the United States, head and neck cancer (HNC) accounts for 66,470 new cases, or 3% of all malignancies, annually.[1] The incidence of HNC is rising, largely driven by increases in oropharyngeal cancer.[2-4] Recent molecular and clinical advancements, particularly with regard to molecular and tumor biology, reflect the heterogeneity of the subsites contained within the head and neck. Despite this, existing guidelines for post-treatment surveillance remain broad without much consideration given to different anatomic subsites and etiologic factors (such as human papillomavirus [HPV] status or tobacco exposure).[5] Surveillance incorporating the physical examination, imaging, and emerging molecular biomarkers is an essential part of care for patients treated for HNC and allows for the detection of locoregional recurrence, distant metastases, and second primary malignancies aiming for better functional and survival outcomes. Additionally, it allows for evaluation and management of post-treatment complications.

INTRODUCTION

HNC surveillance should incorporate a multidisciplinary approach centered on cancer monitoring for both index case and second primary, evaluation and management of function, optimization of quality of life, and management of cancer and treatment-related side effects and toxicity. A comprehensive head and neck physical examination should be performed at every follow-up. Cranial nerves should be evaluated for deficits. Each subsite should be systematically evaluated. Inspection of the oral cavity and oropharynx should include visualization and palpation of the mucous, buccal and gingival membranes, floor of the mouth, anterior two thirds of the tongue, hard palate, base of the tongue, tonsillar fossae, and posterior pharyngeal wall. Special attention should be given to evaluating tongue mobility and trismus. Although nasal speculum can readily allow for evaluation of the anterior nasal cavity, thorough evaluation of the posterior nasal cavity and nasopharynx should be performed with rigid or fiberoptic endoscopy. Otoscopy can be useful in evaluating for otitis media that can be seen in postradiotherapy eustachian tube dysfunction or nasopharyngeal mass. Although indirect mirror examination can be appropriate in certain cases, fiberoptic endoscopy is an otherwise indispensable component of the clinical examination.

FREQUENCY OF SURVEILLANCE

Current recommendations in the National Comprehensive Cancer Network (NCCN) guidelines favor detailed follow-up every 1-3 months for the first year, every 2-6 months for the second year, and every 4-8 months for years 3 through 5.[5] Approximately 80%-90% of all recurrences occur within the first 2 years after completion of treatment, so close surveillance during this period should be emphasized.[6,7] Compared with no follow-up, current surveillance guidelines have shown a gain-of-life expectancy of 0.3-1.5 years for patients with laryngeal cancer.[8] Another study found that mean survival after detection of locoregional recurrence, distant metastases, or second primary tumor was significantly higher in those with routine follow-up compared with those with self-referral (58 *v* 32 months, respectively, $P < .05$).[9] However, other studies did not show significant differences in overall survival with regard to surveillance frequency.[10,11] Despite a lack of clear evidence that prolonged follow-up after 5 years is beneficial, it is generally recommended because of late recurrences and heightened risk of secondary malignancy within the first 10 years, with an overall 10%-20% lifetime risk of developing a second primary tumor.[12-14] Furthermore, recognition and management of late post-treatment complications is important. Those who continue to consume tobacco and alcohol are especially at risk. Adherence to surveillance has been shown to be an independent predictor of survival in the 5-10 years after treatment, again underlining the importance of close observation.[15]

Even so, a more nuanced approach to surveillance could better address the needs of patients. A more recent retrospective study analyzed a novel approach to

PRACTICAL APPLICATIONS

- Surveillance incorporating the physical examination, imaging, and emerging molecular biomarkers is an essential part of care for head and neck cancer (HNC) survivors and allows for the detection of locoregional recurrence, distant metastases, and second primary malignancies aiming for better functional and survival outcomes.
- Current recommendations in the National Comprehensive Cancer Network (NCCN) guidelines favor detailed follow-up every 1-3 months for the first year, every 2-6 months for the second year, and every 4-8 months for years 3 through 5.
- We advocate for a risk-stratified approach to personalize HNC surveillance that accounts for important clinical features, such as initial staging, tobacco use history, and human papillomavirus status.
- Given the absence of a dominant framework for post-treatment surveillance among HNC survivors, the adoption of Neck Imaging Reporting and Data Systems has the potential to add value for patients and providers and personalize imaging algorithms by tumor site, stage, and patient risk factors.
- Molecular biomarkers could prove useful in surveillance as adjuncts to complement physical examination and imaging.

calculating optimal follow-up schedules for various HNC subtypes. Lee et al analyzed a group of 673 patients diagnosed with nasopharyngeal, hypopharyngeal, and HPV-positive and HPV-negative oropharyngeal and laryngeal cancers across two tertiary centers to calculate event-free survival curves and resultant surveillance intervals. Their study identified significantly different follow-up intervals for each subsite, with shortest intervals recommended for hypopharyngeal cancer and longest intervals for HPV-positive oropharyngeal cancer.[16] Furthermore, post-treatment surveillance may be most beneficial for patients with earlier stages of disease. One study found that 87% of patients who survived after recurrence initially had T1 or T2 index tumors and only 30% had nodal disease at the time of primary diagnosis.[17] Despite high adherence to surveillance guidelines, those with more advanced-stage disease unfortunately had poor survival rates overall.[18]

Subsite-driven surveillance schedules should be balanced with a consideration for the patients' overall well-being. The foremost concern for patients after treatment is risk of recurrence.[19] Follow-up can help address therapy-related complications (xerostomia, osteoradionecrosis, hypothyroidism, dental disease, or dysgeusia), voice and swallowing rehabilitation, nutritional support, depression, anxiety, and other comorbid conditions. A systematic review on patient perspectives by McLaren et al found that surveillance was viewed generally positively and brought significant reassurance. However, patients did indicate preferences for higher levels of access to dental professionals and psychological support regarding recurrence.[20] In fact, there are a wide range of cancer and treatment-related complications that affect the oral cavity, regardless of tumor location, associated with impaired quality of life that should be closely managed by dental professionals.[21-23] Furthermore, it is also critical to acknowledge the racial disparities between African American and White patients with HNC; African American patients are more likely to present with advanced disease and have worse outcomes,[24] and subsequent follow-up should focus on addressing these differences.

There is mixed evidence to support routine surveillance compared with symptom-directed surveillance. Nevertheless, it is not always possible to delineate symptoms related to side effects from treatment from tumor recurrence without comprehensive examination and/or imaging. As an example, routine surveillance with clinical follow-up and imaging identified more recurrences and second primaries than symptom-driven monitoring.[9] However, other studies have demonstrated that surveillance driven by patient symptoms is more sensitive at detecting locoregional recurrence than imaging.[10] Beyond its utility in detecting recurrence or secondary malignancy, addressing patient symptomology can improve comprehensive care in this patient population.

IMPACT OF SMOKING STATUS

In addition to its role as a major risk factor for the development of HNC, tobacco use is associated with increased all-cause mortality, cancer-specific mortality, and elevated risk of secondary primary cancers. Furthermore, tobacco smoking during and after therapy has been linked to poorer local disease control, increased risk of cancer progression, and death.[25-27] Despite this, a population-based study found that only 51.7% of individuals with a cancer diagnosis and active tobacco use were counseled on cessation by health care providers.[28] Given that cigarette smoking is a significant risk factor for HNC development, recurrence, and second primary cancers, all health care providers should actively promote cessation of use of all tobacco products (along with avoidance of alcohol consumption). The NCCN recommendations for patients who are smokers highlight the following three principles: (1) evidence-based motivation strategies and behavior therapy, (2) evidence-based pharmacotherapy, and (3) close follow-up with retreatment as needed.[29] Furthermore, the NCCN recommends annual

screening with computed tomography (CT) of the chest for patients with HNC and a history of 20 pack-years of smoking on the basis of their high-risk categorization.

IMAGING AS PART OF SURVEILLANCE

The head and neck is one of the most anatomically complex regions, with unique challenges in interpreting imaging related to complicated postsurgical and postradiation changes and lack of standardization of imaging reporting. This is compounded by an ever-expanding arsenal of treatment options with advances in minimally invasive surgery, therapeutic de-escalation protocols, intensity-modulated radiation therapy, and proton therapy.[30-33] The combination of structural intricacies of the head and neck, need for careful monitoring after treatment, and large growing population of HNC survivors[34] underscore the need for optimal surveillance regimens and standardized reporting. Standardized reporting will, in turn, facilitate data gathering to further refine the best surveillance algorithms by tumor subsite, stage, biology, and risk factors.

IMAGING MODALITIES AND TECHNIQUES

Imaging modalities, such as CT, positron emission tomography (PET)/CT, and magnetic resonance imaging (MRI), play a critical role in diagnosis, staging, treatment, and surveillance of cancers involving the head and neck.[35] There are also emerging techniques, such as PET/MR[35] and dual-energy contrast-enhanced CT (CECT) for surveillance imaging, which have shown promising results.[36] Ultrasound has been widely used in the detection, risk stratification, and surveillance of uncomplicated thyroid malignancy[37] and image-guided biopsies. Most HNC imaging for staging and treatment planning includes a neck CECT for less advanced tumors with the addition of chest CT and/or PET/CT for more advanced tumors.

MRI with contrast has superior soft-tissue resolution, particularly when malignancy involves the intracranial structures, skull base, orbit, perineural disease, or deep fascial planes.[38,39]

Therefore, MRI surveillance is best for tumors in the nasopharynx, sinonasal cavities, skull base, orbits, face, salivary glands, and cutaneous tumors with perineural spread.[35] Alternatively, CECT with or without PET/CT is more commonly used for cancers involving the oropharynx, oral cavity, larynx, and hypopharynx because intracranial, orbital, and perineural extensions from these subsites are less common.[40]

Although the current NCCN guidelines recommend imaging after treatment within the first 6 months, there is no official recommendation for surveillance imaging in an asymptomatic patient beyond 6 months, leading to extreme variation in clinical practice on the basis of institution and oncologist and surgeon preference.[41,42] Among the challenges in post-treatment imaging surveillance are variation from normal anatomy and the lack of standard lexicon to describe findings on post-treatment imaging.

NECK IMAGING REPORTING AND DATA SYSTEMS LEXICON AND RISK CATEGORIES

The American College of Radiology (ACR)-Neck Imaging Reporting and Data Systems (NI-RADS) committee attempted to address these limitations with (1) standardized lexicon and reporting template with risk categories and (2) guidelines for the timing and modality for imaging surveillance.[43] NI-RADS[44] and other lexicon and categorization systems for cancer surveillance[45-48] have streamlined communication between radiologists, clinicians, and patients, which have proven invaluable in guiding management.

An ACR committee developed the NI-RADS for surveillance CECT imaging with or without PET in patients with treated HNC in 2018[48] and subsequently developed a template for contrast-enhanced MRI in 2022. NI-RADS offers a comprehensive imaging-based risk stratification system and framework for HNC surveillance to create a shared language that links easily to actionable management steps.[48-50] Furthermore, NI-RADS serves to simplify communication, standardize nomenclature and reporting across institutions, and facilitate ongoing data collection.[48] Standardized scores are assigned based on the interpreting radiologist's perceived risk for recurrent or residual disease or inability to adequately assess. The primary site (local recurrence; Fig 1) and the neck (regional recurrence; Fig 2) are each assigned an ordinal score from 0 to 4, which in turn corresponds to management guidelines by modality (Figs 3 and 4) that may or may not be appended to the radiology report.

Unlike other tumor-reporting systems that record only a single data point, such as size, in the RECIST criteria or fluorodeoxyglucose (FDG) uptake, NI-RADS incorporates many data points, including morphology, contrast enhancement, superficial versus deep location, FDG avidity, and MRI signal characteristics (diffusion and even timing after treatment). Consideration of these collective data points adds value for each patient. Size alone is not even considered in NI-RADS as it is a flawed measurement alone to determine the presence or absence of disease in HNC. Furthermore, irregularly shaped mucosal primaries and complex post-treatment appearances create unique challenges for target measurements. The Hopkins criteria[51] is a reporting tool to quantify FDG uptake and can easily be applied to NI-RADS.

NI-RADS SURVEILLANCE MODALITY AND TIMING

The ACR NI-RADS recommendation for surveillance reflects a combination of the current and past literature, various multidisciplinary institutional approaches, and consensus of the ACR committee members, which are detailed below.[48]

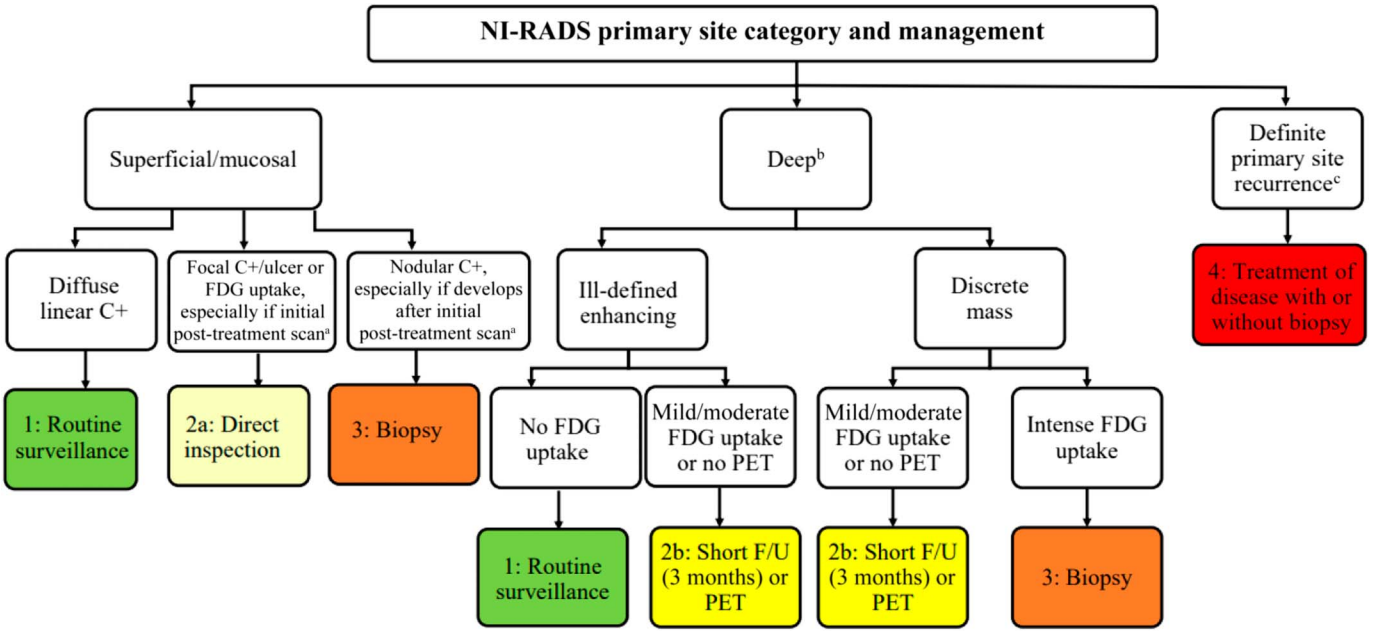

FIG 1. NI-RADS primary site category and management. [a]Most mucosal abnormalities are assigned NI-RADS category 2a as the surgeons or oncologists can best assess the mucosal surfaces, and focal mucosal abnormalities have a high likelihood of being treatment related on the initial post-treatment scan. However, more mass-like mucosal or very superficial submucosal abnormalities can be upgraded to NI-RADS category 3, especially if they develop after the post-treatment baseline study. [b]Outside of the post-treatment baseline study, surveillance may be done with a CECT or MRI without a PET. Recommendation for PET may be NI-RADS category 2 management. [c]On the basis of pathologic confirmation or definitive radiologic progression, biopsies may be needed so that patients can enroll in a trial or otherwise continue with treatment. CECT, contrast-enhanced computed tomography; FDG, fluorodeoxyglucose; F/U, follow-up; MRI, magnetic resonance imaging; NI-RADS, Neck Imaging Reporting and Data Systems; PET, positron emission tomography.

- PET/CECT (with diagnostic neck CT) at 8-12 weeks after completion of definitive therapy as a baseline;
- if this is negative, a CECT 6 months later;
- if CECT is negative, a CECT of the neck alone 6 months later (if two consecutive PET/CECTs are negative, consider stopping surveillance imaging); and
- if second CECT is negative, CECT of the neck and chest at 12-month intervals.

MRI is often woven into and may replace CECT in this same general algorithm for tumors in and around the skull base, and emerging PET/MRI protocols may offer the advantage of streamlining surveillance in many cases, such as nasopharyngeal cancer. Early studies suggest that PET/MRI may improve the evaluation of tumor extension compared with PET/CT in certain HNC.[35] For example, instead of using MRI to follow the primary site and then using PET/CECT for regional and distant disease, it may be advantageous to use PET/MR to accomplish all three.

The inclusion of PET with CECT for the initial restaging baseline, especially in patients treated with up-front chemoradiation, is recommended to have the best combination of sensitivity and negative predictive value (NPV). Much of the current literature is based on noncontrast PET/CT interpreted by nuclear medicine specialists alone, rather than PET with CECT interpreted with a neuroradiologist. CECT with PET appears superior to CECT alone as initial post-treatment surveillance imaging.[52,53] A lack of FDG avidity in soft tissues located in the area of regressed lymphadenopathy on initial post-treatment PET/CT demonstrates an NPV of 90%-100%.[54] On the other hand, noncontrast PET/CT without a diagnostic CECT of the neck has increased the likelihood of false positives without the superior anatomic detail of a CECT and without the expertise of a diagnostic radiologist. Obtaining surveillance imaging immediately after the completion of therapy can lead to false positives.[55]

NI-RADS has shown good discrimination and risk stratification, with positive recurrence rates ranging from 1% to 3.8% for NI-RADS category 1, 5.6% to 17% for NI-RADS category 2, 59.4% to 66.7% for NI-RADS category 3, and 100% for NI-RADS category 4, with recent studies further refining on the basis of primary versus regional recurrence.[44,56] NI-RADS categories 1 and 2 have shown good NPV (85%-91%) on first post-treatment surveillance imaging.[57,58] Another study found a positive predictive value (PPV) of 56% for NI-RADS category 3 at the primary, 65% in the neck, and 79% at distant sites, with a PPV of 100% for NI-RADS category 4.[59] In the absence of a dominant framework for post-treatment surveillance in HNC survivors, the adoption of NI-RADS has the potential to

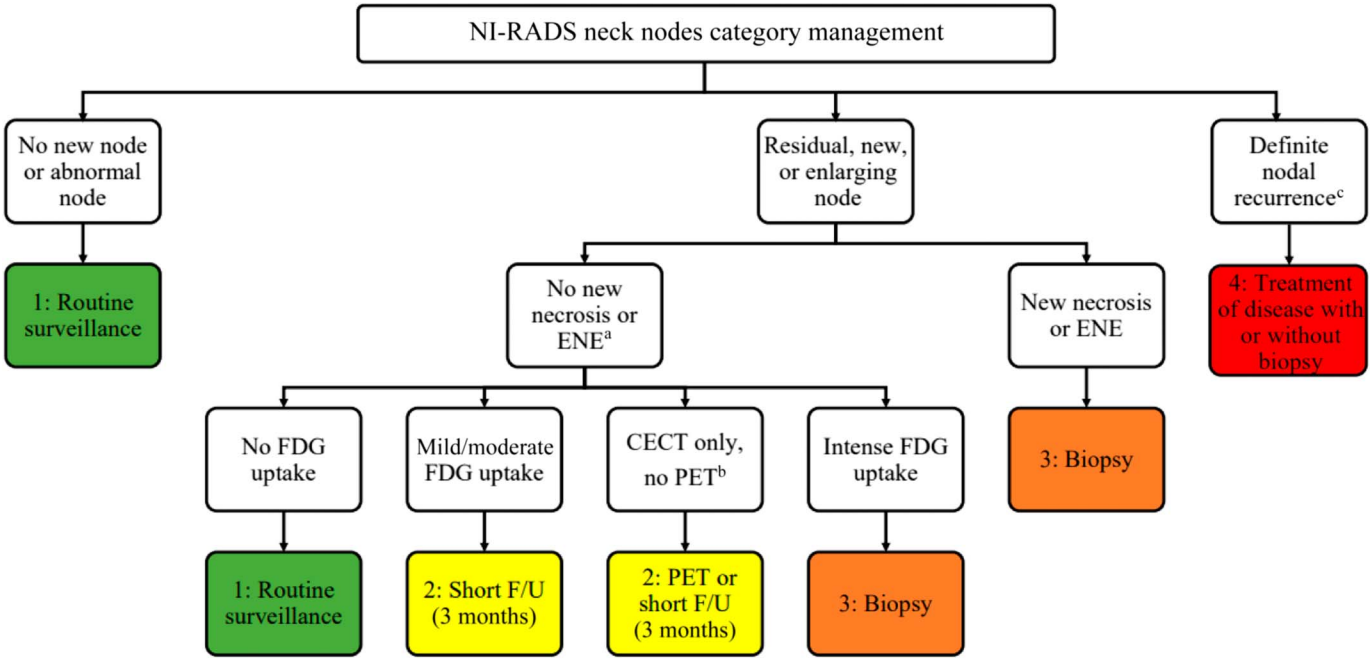

FIG 2. NI-RADS neck nodes category and management. [a]Treated pathologic nodes can have central low density/rim enhancement/necrosis and are scored NI-RADS category 1 if there is no FDG uptake. [b]Newly enlarging node on a CECT alone, without definite morphologically abnormal features, could be given NI-RADS category 2 with recommendation for PET. FDG activity can be used to downgrade to NI-RADS category 1 or upgrade to NI-RADS category 3. [c]On the basis of pathologic confirmation or definitive radiologic progression, biopsies may be needed so that patients can enroll in a trial or otherwise continue with treatment. CECT, contrast-enhanced computed tomography; ENE, extra nodal extension; FDG, fluorodeoxyglucose; F/U, follow-up; NI-RADS, Neck Imaging Reporting and Data Systems; PET, positron emission tomography.

add value for patients and providers and personalize imaging algorithms by tumor site, stage, and patient risk factors.

MOLECULAR BIOMARKERS IN SURVEILLANCE

Circulating or liquid biomarkers are of interest in HNSCC. These cancers can release heterogeneous circulating tumor cells that have been associated with later disease stage and recurrence risk, but detection sensitivity may be limiting.[60] Circulating tumor DNA (ctDNA) arises from apoptotic or necrotic tumor cells and offers a chance to capture unique somatic mutations found in the cancer.[61] Furthermore, tumor cell–secreted vesicles (exosomes) can carry molecular elements or which can also be detected in circulation.[62]

HPV ctDNA

HPV-positive oropharyngeal carcinoma (HPV+ OPC) is characterized by favorable survival characteristics, but up to 20% of patients relapse with locoregional or distant metastatic spread.[63] Relapses can occur late in the disease natural history, and patients presenting with oligometastatic disease can sometimes be treated with curative intent, underscoring the value of early recurrence detection.[64] ctDNA has emerged as a diagnostic tool to detect the presence of cancer or quantify tumor burden.[65] Given that OPC is often causally linked to high-risk HPV subtypes with viral DNA integrated into the host cell genome, this represents an ideal model with which to apply ctDNA.[66] Droplet digital PCR is a newer method that facilitates ultrasensitive detection of even single copies of DNA permitting monitoring and quantification of low-level targets. Recent tests for circulating, cell-free tumor tissue–modified viral (TTMV)-HPV DNA have been developed to distinguish tumor-associated HPV DNA,[67,68] yielding a unique biomarker produced during the fragmentation or shed of integrated or episomal HPV DNA.

A series of observational cohort studies have shown that HPV DNA in both oral rinses and plasma (Table 1) precedes clinical detection of disease recurrence.[74] When considering these data in aggregate, accuracy characteristics seem to depend on the sample tested (favoring plasma over oral rinses), the assay detection methods, and the site of recurrent disease (locoregional *v* distant). Notably, high NPV seems consistent across these cohorts at 89%-100% such that patients with recurrent or active disease would be unlikely to have an undetectable result—findings that appear comparable with PET/CT imaging.[75,76] To our knowledge, the largest data set to date was published in 2022 by Berger et al[73] demonstrating a 95% NPV among 1,076 patients across hundreds of participating centers using the commercially available, plasma-based NavDx (TTMV)-HPV DNA assay (Naveris, Waltham, MA). Although prospective data are needed, these collective findings suggest that

NI-RADS™ PET/CT Category Descriptors, Imaging Findings, and Management

Category	Primary Site	Neck	Imaging Findings		Management
			Primary Site	Neck	
Incomplete	**0**	**0**	New baseline study without any prior imaging available ***AND*** knowledge that prior imaging exists and will become available as comparison		Assign score in addendum after prior imaging examinations become available
No evidence of recurrence	**1**	**1**	Expected post-treatment changes Non-mass-like distortion of soft tissues Low-density post-treatment mucosal edema Diffuse linear mucosal enhancement or FDG If residual nodal tissue, no FDG uptake or enhancement		Routine surveillance
Low suspicion	**2a**	**2**	Focal mucosal enhancement or FDG uptake on initial post treatment scan[a]	Mild/ mod FDG in residual nodal tissue or persistent areas of heterogenous enhancement Enlarging or new lymph node without definitive abnormal morphologic features[a] Any discordance between PET and CECT: enlarging lymph node but little to no FDG uptake[b]	2a: Direct visual inspection
	2b		Deep, ill-defined soft tissue, with only mild/ moderate FDG if PET available Any discordance between PET and CECT: discrete CECT abnormality but little to no FDG uptake or focal FDG uptake but no CT correlate[b]		2b or neck 2: Short interval follow-up (3 months) or PET if scoring on CECT alone
High suspicion	**3**	**3**	Discrete nodule or mass at the primary site with intense focal FDG uptake if PET available Residual nodal tissue with intense FDG New enlarged lymph node or enlarging lymph node with abnormal morphologic features[c] on CECT only or focal intense FDG uptake if PET available		Image-guided or clinical biopsy if clinically indicated
Definitive recurrence	**4**	**4**	Pathologically proven or definite radiologic and clinical progression		Clinical management

FIG 3. NI-RADS PET/CT surveillance key. [a]Focal mucosal abnormalities have a high likelihood of being treatment related, especially on the initial post-treatment PET/CECT, so that in most cases, it is prudent to assign a 2a and let surgeons or oncologists directly inspect. If a more mass-like or nodular mucosal abnormality develops later in the time course of surveillance, it may warrant a 3. [b]This guideline for PET and CECT discordance only applies if the original tumor was FDG avid. [c]Morphologically abnormal features that are definitive = new necrosis or gross ENE as evidenced by invasion of adjacent structures. (1) Residual nodal tissue = node that was abnormal and identified on pretreatment scan. In these cases, hypoenhancement and irregular borders are not unexpected and are likely a sign of treatment response, especially if there is no FDG uptake. (2) New or enlarging node = node that develops during surveillance (not on pretreatment scan). In these nodes, irregular borders or necrosis are definitively abnormal features. If primary tumor is unknown, the authors suggest designating P-unknown primary; if the primary cannot be assessed (dental artifact, motion, or other technical reasons or outside FOV), the authors suggest P-x. NI-RADS categories are designed for use after definitive/curative treatment for HNC and are therefore not designed to be used during treatment. CECT, contrast-enhanced computed tomography; CT, computed tomography; ENE, extra nodal extension; FDG, fluorodeoxyglucose; FOV, field of view; HNC, head and neck cancer; NI-RADS, Neck Imaging Reporting and Data Systems; PET, positron emission tomography.

NI-RADS™ MRI Category Descriptors, Imaging Findings, and Management

Category	Primary Site	Neck	MR Imaging Findings: Primary Site	MR Imaging Findings: Neck	Management
Incomplete	0	0	New baseline study without any prior imaging available ***AND*** knowledge that prior imaging exists and will become available as comparison		Assign score in addendum after prior imaging examinations become available
No Evidence of Recurrence	1	1	Expected posttreatment changes Diffuse thin linear mucosal enhancement or submucosal edema Low T1 and T2 signal intensity suggesting scar/fibrosis Non-mass-like distortion of soft tissues with T2-hyperintense (not T2-intermediate) signal, suggesting edema / inflammation *Note: Be familiar with appearance of flaps (which often have different enhancement and signal characteristics than the original tumor)*		Routine surveillance
			Comparison with prior post-treatment studies available: No new focal nodular or mass-like soft tissue Unchanged or decreased effacement of fat planes on pre-contrast T1WI and/or unchanged or decreased enhancement at skull base foramina and in perineural locations	Residual nodal tissue[b] that is hypoenhancing in the region of original node, and no FDG uptake if PET is available	
	1f		***First post-treatment baseline study***[a]: Resolution of tumor seen on pre-treatment study; no focal nodular or mass-like soft tissue Decreased soft tissue and/or enhancement in skull base foramina and perineural regions, decreased effacement of fat planes on pre-contrast T1WI		
Low Suspicion	2a	2	Focal non-mass-like mucosal enhancement[c] or focal reduced diffusion	Residual nodal tissue with persistent areas of heterogeneous enhancement or mild/moderate FDG uptake if PET is available New or enlarging lymph node[f] without definitive abnormal morphologic features Any discordance between PET and MRI if PET or PET/MRI is available: enlarging lymph node or discrete neck mass but little to no FDG uptake, or focal uptake with no MRI correlate[g]	Primary 2a: Direct visual inspection
	2b		Deep, ill-defined non-nodular soft tissue Soft tissue in which MRI features are different from the original tumor: different DWI, enhancement, or T1 and T2 signal characteristics (and therefore considered 2b rather than 3)[d] Soft tissue with intermediate rather than hyperintense T2 signal and intermediate rather than intense enhancement (and therefore considered 2b rather than 1)[e]		Primary 2b or 2f, or Neck 2: Short interval follow-up MRI or PET to assess deep submucosal abnormality or questionable nodes. *Note: PET is not as helpful for evaluation of perineural disease at the skull base. As such, for a Primary 2b or 2f related to perineural soft tissue, short interval follow-up MRI would be preferable over PET.*
	2f		***First post-treatment baseline study***: Partial resolution of tumor when compared to pre-treatment study No change in soft tissue in skull base foramina and perineural regions which is of same signal and enhancement characteristics when compared to pre-treatment study New thin smooth enhancement in skull base foramina and perineural regions within radiation field		
High Suspicion	3	3	Discrete nodule or mass at the primary site especially if new/enlarging ***AND*** signal characteristics and enhancement match original tumor Intense focal FDG uptake if PET is available Increased soft tissue and/or enhancement in skull base foramina and perineural regions, increased effacement of fat planes and skull base foramina on pre-contrast T1WI, and/or increased enhancement and nodular soft tissue along major nerves supplying the site of primary disease	Residual nodal tissue with intense FDG uptake ***OR*** definite enlargement/ increased enhancement New or enlarging lymph node[f,f] with necrosis or irregular borders, or focal intense FDG uptake if PET is available	Image-guided or clinical biopsy if clinically indicated
Definitive Recurrence	4	4	Pathologically proven or definite radiologic and clinical progression		Clinical management

FIG 4. NI-RADS MRI surveillance key. [a]The first post-treatment MRI serves as a new baseline study for the future comparison. On the first post-treatment MRI, skull base foramina and perineural findings are indeterminate (in the absence of features suspicious for residual or progressive tumor (continued on the following page)

FIG 4. (Continued). described under NI-RADS categories 2 and 3) and can be presumed to be post-treatment related and assigned NI-RADS category 1, until further assessment on the next MRI. [b]Residual nodal tissue = tissue as a site where an abnormal node was present and identified on pretreatment scan. In these cases, hypoenhancement and irregular borders are not unexpected and are likely a sign of treatment response, especially if there is no FDG uptake. [c]Focal mucosal abnormalities have a reasonable likelihood of being treatment-related, especially on the initial post-treatment study, such that, in most cases, it is prudent to assign NI-RADS category 2a and recommend correlation with direct visual inspection. If a more mass-like or nodular mucosal abnormality develops later in the time course of surveillance, the assignment of NI-RADS category 3 may be warranted. [d]If there is persistent enlargement or growth of discrete mass-like soft tissue that differs in signal characteristics from the original tumor, this should be designated NI-RADS category 3 despite the mismatch in signal characteristics. [e]Tumor tends to exhibit intermediate T2 signal and enhancement, white hyperintense T2 signal and intense enhancement are more often seen with reactive/inflammatory changes. [f]New or enlarging node = node that newly develops or grows during the course of surveillance (node not present or smaller on pretreatment scan). In these nodes, irregular borders or new necrosis are definitively abnormal features. Irregular borders with new gross ENE as evidenced by invasion of adjacent structures is another abnormal feature. This is in contradistinction to irregular border or necrosis in nodes unchanged or decreasing in size after radiation treatment, which are considered expected post-treatment findings in radiated nodes. [g]This guideline for PET and MRI discordance only applies if the original tumor was FDG avid. If the primary tumor is unknown, the authors suggest designating P-unknown primary; if the primary cannot be assessed (dental artifact, motion, or other technical reasons or outside FOV), the authors suggest P-x. Head and neck surveillance MRI examinations are often tailored to a specific area of concern (eg, skull base for perineural tumor spread), in which case the entire neck may not be imaged. If the neck cannot be assessed, the authors suggest N-x. NI-RADS categories are designed for use after definitive/curative treatment for HNC and are therefore not designed to be used during treatment. DWI, diffusion weight imaging; ENE, extra nodal extension; FDG, fluorodeoxyglucose; FOV, field of view; HNC, head and neck cancer; MRI, magnetic resonance imaging; NI-RADS, Neck Imaging Reporting and Data Systems; PET, positron emission tomography; T1WI, T1 weighted image.

guideline recommended clinical surveillance intervals might be modified or reduced in the future among those with undetectable HPV ctDNA during surveillance. This notion is likely to have a broader long-term economic impact, where cost modeling predicts a potential for future health care cost-savings with HPV ctDNA incorporation.[77]

HPV ctDNA assay performance in detecting disease recurrence has been somewhat variable, with PPVs ranging from 63% to 100%.[78] Again, the largest data series to date initially reported a PPV of 95% (updated to 97.5%),[73] and in many independent cohorts, there is a notable median lead time between a positive test result and a confirmation of recurrence (on imaging or biopsy) ranging from 2 weeks to 10 months.[68] Prospective studies, such as NCT04965792, will help clarify how often HPV ctDNA testing should occur during surveillance to complement clinical examination and imaging time points. A newly detectable HPV ctDNA result during surveillance should raise concern, and some argue should prompt short-interval retesting, an updated examination, and reflex PET/CT imaging. In the setting of locoregional disease, baseline HPV ctDNA values do associate with cervical lymph node involvement,[78] but absolute values or cutoffs do not currently inform disease burden or site. Furthermore, providing HPV ctDNA testing may affect patient-reported fear of recurrence.

On the basis of these data and the commercial availability of the NavDx platform, some have adopted the use of plasma (TTMV)-HPV DNA into routine surveillance practice for patients with HPV+ OPC while others await prospective data and national guideline recognition.

Epstein-Barr Virus ctDNA

Epstein-Barr virus (EBV) is endemically linked to nasopharyngeal carcinoma (NPC) particularly in Northern Africa and Southeast Asia.[79] Previous studies have collectively demonstrated that elevated plasma EBV ctDNA may be useful for screening and early disease detection.[80] Large prospective trials have reported high sensitivity and specificity in screening endemic patients for NPC with EBV ctDNA.[81] Furthermore, clearance of EBV ctDNA after chemoradiation has been shown to inform treatment response,[81] and recrudescence of detectable values after curative-intent therapy predicts recurrence. Moreover, post-treatment detectable EBV ctDNA predicts worse survival outcomes.[82] Although variability in assay performance and meaningful cutoffs for detection have

TABLE 1. Studies Investigating Human Papillomavirus ctDNA for Recurrent Disease Detection

Study	Treatment	Median Lead Time, months (range)	No. of Patients	PPV, %	NPV, %
Ahn et al[69]	S, R, or both	4.4	52	83.3	93.5
Chera et al[68]	R	3.9 (0.4-12.9)	115	94.0	100.0
Reder et al[70]	S, R, or both	—	23	62.5	100.0
Rutkowski et al[71]	R	—	216	83.0	100.0
Tanaka et al[72]	R	10	35	100.0	89.7
Berger et al[73]	Any	—	1,076	95.0	95.0

Abbreviations: ctDNA, circulating tumor DNA; NPV, negative predictive value; PPV, positive predictive value; R, radiation; S, surgery.

been cited as concerns, many clinicians use EBV ctDNA monitoring as part of NPC surveillance.

ctDNA

Beyond viral ctDNA as a liquid biomarker for surveillance, more than half of advanced HNC patients may yield detectable plasma (nonviral) ctDNA.[82,83] Several commercial assays are now available (Signatera, Seraseq, Invitae PCM, Guardant360, Sysmex Inostics HNSCC-SEQ, etc) with data emerging in various solid tumor types. Recent studies show that even among early-stage HNCs, plasma and/or oral salivary detection of somatic mutations, such as *TP53*, *PIK3CA*, *NOTCH1*, *FAT1*, *CDKN2A*, *CASP8*, *FBXW7*, and/or *HRAS*, is feasible.[84,85] The high frequency of *TP53* loss-of-function mutations and *CDKN2A* inactivation in carcinogen-related HNSCC and *PIK3CA* mutations in HPV+ HNSCC make these obvious candidate biomarkers,[86] with *TP53* most commonly detected overall.[87,88] However, even when both oral and plasma samples are tested together, ctDNA detection rates can be variable.[82,89,90] Furthermore, clearance studies suggest that ctDNA half-life is limited to hours to days.[91] One recent study demonstrated ctDNA detection among five of seven patients with HNSCC who later developed recurrence, but not among 13 recurrence-free cases, and observed that ctDNA detection was more sensitive than imaging.[92] To date, most ctDNA studies in HNSCC present an aggregate of total somatic mutations rather than specific mutational distributions and are limited by small, single institutional bias.

ctDNA Gene Methylation

Expanding on plasma-based ctDNA, tumor-derived fragmented DNA may undergo epigenetic changes or methylation, which typically leads to gene silencing. Since tumor heterogeneity is inherent and somatic mutations may occur at low frequency, detecting methylated ctDNA may have added value.[93] For the present, early studies in HNSCC suggest that ctDNA genetic methylation may occur more frequently compared with cancer-free controls.[94] Diagnostic test characteristics vary widely among hypermethylation assays, and future investigations are needed.

Exosomes

Virus-sized extracellular vesicles can contain a number of proteins or micro(mi)-RNA released from tumor cells and are found in various bodily fluids. Recent data suggest that plasma exosomes may be more prevalent in patients with HNSCC and differential shed may exist based on HPV status.[95] Furthermore, isolated exosomes from patients with HNSCC have yielded differential PD-L1 and miRNA levels that appear associated with disease stage[96,97]—an active area of investigation that also interplays with the tumor immune microenvironment.

CONCLUSIONS

Surveillance for the HNC survivor should incorporate physical examination, imaging, and emerging molecular biomarkers to promote early recurrence detection and identification of second primary malignancies to optimize functional and survival outcomes. NI-RADS should be adopted to guide imaging interpretation, timing, and modality choice during HNC surveillance. Molecular biomarkers, such as HPV ctDNA, could prove useful in clarifying minimal residual disease status beyond what examination findings and imaging can detect. The authors advocate for a risk-stratified approach to personalize surveillance that accounts for important clinical features, such as initial staging, tobacco use history, and HPV status.

Shared Decision Making in the Care of Patients With Cancer

Salma Shickh, PhD[1,2]; Konstantinos Leventakos, MD, PhD[3,4]; Mark A. Lewis, MD[5]; Yvonne Bombard, PhD[1,2,6]; and Victor M. Montori, MD, MSc[3]

overview

Shared decision making (SDM) is a method of care that is suitable for the care of patients with cancer. It involves a collaborative conversation seeking to respond sensibly to the problematic situation of the patient, cocreating a plan of care that makes sense intellectually, practically, and emotionally. Genetic testing to identify whether a patient has a hereditary cancer syndrome represents a prime example of the importance for SDM in oncology. SDM is important for genetic testing because not only results affect current cancer treatment, cancer surveillance, and care of relatives but also these tests generate both complex results and psychological concerns. SDM conversations should take place without interruptions, disruptions, or hurry and be supported, where available, by tools that assist in conveying the relevant evidence and in supporting plan development. Examples of these tools include treatment SDM encounter aids and the Genetics Adviser. Patients are expected to play a key role in making decisions and implementing plans of care, but several evolving challenges related to the unfettered access to information and expertise of varying trustworthiness and complexity in between interactions with clinicians can both support and complicate this role. SDM should result in a plan of care that is maximally responsive to the biology and biography of each patient, maximally supportive of each patient's goals and priorities, and minimally disruptive of their lives and loves.

SHARED DECISION MAKING IN THE CARE OF PATIENTS WITH CANCER

Shared Decision Making as a Method of Care

In recent years, the field of cancer treatment has seen a significant increase in the availability of treatment options, including immunotherapy, targeted therapies, and multidisciplinary care, which are being offered to almost every patient with cancer. Simultaneously, individuals living with cancer are exposed to a multitude of informational channels, including social media, which provide them with information about their disease and possible treatments.[1] The complexity of cancer care and the abundance of cancer-related information complicate the development of care plans that make sense for each person. Cocreation of such plans may lead to plans that maximally support patient priorities, respond well to the patient's situation, and minimally disrupt their lives and loves.[2] Doing so may also increase patient satisfaction with treatment, boost confidence in the plan of care, and improve trust in the medical team.[3]

Shared decision making (SDM) is a collaborative approach to care by which patients and their clinicians work in partnership to address the problematic situation of the patient and respond by cocreating sensible plans of care.[4,5] SDM begins with determining the nature of the patient's situation, which often involves insights that only the patient and their family can provide, including aspects of the patient's biology (the nature of the cancer itself and of the health state and comorbidities of the patient) and biography (the personal history of the patient, social and economic contexts including forms of discrimination, exclusion, and injustice; their relationships and responsibilities; and their expectations and dreams) and their mutual interactions.

In the case of cancer care, clinicians must work with patients, with competence and compassion, to develop a practical cancer care plan that is informed by relevant evidence, addresses emotional aspects of the problem, and is both feasible and sustainable for the patient.[6,7] Seen in this way, SDM is not an additional task for clinicians but a fundamental method of care that is central to the clinician's art, similar to history taking, physical examination, selection and interpretation of diagnostic tests, and patient education and counseling.[8]

How Can SDM Contribute to the Care of Patients With Cancer?

We have previously described how to implement SDM in practice[8]; these steps can easily be translated in everyday cancer care practice.

Foster a productive conversation. The initial step involves promoting productive dialogues that encourage

Author affiliations and support information (if applicable) appear at the end of this article.

PRACTICAL APPLICATIONS

- Shared decision making (SDM) is a method of care on the basis of conversations conducted to arrive at a cocreated plan of care that addresses the problematic situation of each patient.
- Unhurried conversations, SDM tools, and collaborative deliberation methods are essential to coproduce care plans.
- Health care systems that favor the processing of people rather than the care of patients are hostile to methods of patient-centered care, such as SDM, and must be radically reformed.
- The experience of patients contributing to care that fits requires access to trustworthy information and expertise within and between clinical encounters.

active patient-clinician collaboration, facilitate the process of care plan development, and support the cocreation of a comprehensive care plan.[9] Throughout the patient's journey, from screening to cancer diagnosis, treatment, and end-of-life discussions, the clinician is tasked with exploring with curiosity the patient's problematic situation, identifying any changes in their health status, concerns, or shifts in their life circumstances. This crucial phase involves the clinician's ability to understand the patient's condition and assess the effectiveness, feasibility, and desirability of the current care plan. It is particularly critical in cancer care, where biologic parameters such as laboratory tests and imaging, alongside other factors such as treatment burden,[10,11] financial toxicity,[12,13] and insurance coverage,[14] contribute significantly to the patient's problematic situation.

The SDM team—patients and clinicians—engages in a continuous and collaborative process of noticing and responding, striving to arrive at an approach that makes sense intellectually (ie, reflects the situation as understood and the response is based on the best available evidence),[5,15] practically (ie, given our understanding of what capacity can be mobilized, what may prove to be feasible to implement in the life routines of the patient, and within what is available in the health care system), and emotionally (ie, addresses, responds, and supports the emotional experiences and feelings of those involved).

Through a thorough examination of the available actions (including those that the parties can identify, uncover, or invent) to address the situation, the team may need to reframe the issue and reformulate the problem at hand.[9] For instance, a patient facing a cancer diagnosis with poor prospects for a cure may initially seek aggressive treatment but may ultimately reframe the situation as one of the seeking ways to achieve a peaceful and dignified death. In such cases, alternative options must be identified, evaluated, and implemented as needed. Throughout this process, the patient plays a critical role in determining the extent to which the plan of care is likely to be effective, feasible, and compatible with other treatments and daily routines, that is, to what extent care fits at the point of life.

Purposefully select and adapt the SDM process. There are four distinct ways in which patients and clinicians can work together to address the patient's problematic situation: (1) focusing on matching preferences, (2) reconciling conflicts, (3) problem-solving, or (4) meaning making.[9] Each of these forms of SDM and representative applications in cancer care are given in Table 1.

In our experience, clinicians and patients who do SDM well work within a form of SDM until a better one becomes apparent and they flexibly, gracefully, and perhaps intuitively switch according to the challenges uncovered during the conversation.[16]

Protect the space (and quality time) for SDM. For SDM to be effectively conducted, it is essential for both patients and clinicians to engage in the process. The conversation itself serves as the primary workspace within which this collaborative work takes place. As such, it is crucial that the conversation space are deliberately designed to promote and facilitate the SDM process.[17] In today's world, this conversation space may take the form of remote consultations[18] and virtual platforms because of the widespread adoption of telehealth in oncology care.[19,20] To ensure a conducive environment, clinicians vigilantly eliminate any visual or auditory distractions that may impede the decision making process. This involves protecting the conversation space and the allocated time for these consultations. Policies must be implemented to safeguard the sacred time of consultation with patients and minimize electronic medical record burdens to eliminate any potential disruptions or interruptions. It is paramount that clinicians (and those whose job is to support care) take these measures to optimize the SDM process and ultimately improve patient outcomes.

Make the most of participation. Having set the stage for an unhurried conversation,[17] it is necessary to determine who should participate in that conversation, including patient caregivers and other significant people in the patient's life as well as clinicians from other specialties with a stake in the decision, a common situation given the high prevalence of multidisciplinary care. Multidisciplinary clinics and multidisciplinary cancer care patient navigators can help to avoid confusion and secure better coordination of care. These stakeholders can take part or assist the established patient–clinician dyad in cocreating a plan of care.

TABLE 1. Forms of SDM (adapted from the study by Montori et al[8])

SDM Form Method Description	Situations in Which This Form May Be Preferred
Matching preferences	
Patients and clinicians compare features (ie, efficacy, burdens, side effects) of the available options and match them with the patient's values, preferences, goals, and priorities. They may use an SDM tool to share information about the options. Patients and clinicians deliberate until the best match is identified	Patients and clinicians discuss options for adjuvant treatment in early-stage resected lung cancer
Reconciling conflicts	
Using a collaborative process, the clinician helps the patient articulate the reasons for their position while reconciling those reasons with the varying possibilities ahead	Patients and clinicians discuss options for clinical trial participation when the patient is afraid of being treated with placebo—while there is no placebo in this trial
Problem-solving	
Potential solutions are tested—in conversation or therapeutic trials—and become justified on the basis of the extent to which these can demonstrably and successfully address the problem and improve the patient's situation	Patients and clinicians discuss different ways in which the toxicity of a systemic therapy can be managed and mitigated given the comorbidities of the patient
Meaning making	
Using conversations, patients and clinicians develop insight into what the patient's situation means, at a deep level, to the patient and their community and to find the reasons within that process for pursuing a particular approach	Patients and clinicians seek to make sense of the lack of cancer response to therapy and develop a way to frame the situation and bring patient, family, and others into a joint understanding that the patient care has new goals and approaches

Abbreviation: SDM, shared decision making.

Deploy useful tools. To facilitate effective SDM, it is important for both clinicians and patients to carefully consider the tools that are introduced into the conversation. This includes specialized tools that have been specifically designed to support forms of SDM that have demonstrated effectiveness, usability, and desirability. Depending on the circumstances, various tools can be used to aid in the decision making process, such as self-management logs, patient-reported outcome trends, and results from ancillary laboratory and imaging tests, all of which can support the problem-solving mode of SDM. One notable tool is the My Healthcare, My Life conversation tool.[21,22] This tool is specifically designed to foster a mutual understanding between patients and clinicians regarding the social and economic challenges that patients may encounter on a regular basis and how these factors may affect their health and the implementation of treatments.

The Making of an SDM Tool

The team at the Knowledge and Evaluation Research (KER) Unit is one of the several groups worldwide which has been developing and evaluating SDM tools.[23] The KER Unit has been working on this for more than a decade, pioneering user-centered design and participatory action research in clinical practice.[24]

Our process follows the steps described in Figure 1:

1. Assemble a multidisciplinary team comprising designers, patients, oncologists and other clinicians, decision making scientists, and a stakeholder group comprising oncologists, primary care clinicians, patients, a designer, and other stakeholders.
2. Consult with a Patient Advisory Group—a group of 8-10 volunteer patients living with the condition of interest who engage with developers to ensure that the work is pertinent and responsive to patient priorities. This group helps identify relevant outcomes that must be considered in both the evidence synthesis and the SDM tool.
3. Synthesize the evidence about the benefits and potential harms and inconveniences of potential cancer treatments including existing practice guidelines. If pertinent, after reviewing the results with the stakeholder group, we produce an evidence table that outlines the efficacy, harms, and practical implications for each management option (ie, adjuvant treatment or surveillance).
4. Conduct observations of current treatment conversations between patients and their oncologists. Over 95% of clinicians and patients routinely consent for video recording. We use institutional review board–approved procedures for obtaining and securely storing the recordings and accessing them with rigorous protection of patient and clinician privacy.
5. Design a first prototype—using information from the evidence synthesis, insights about outcomes and practical considerations from our patient advisory group and on the basis of what is hard or difficult in existing, directly observed, conversations, an experienced interaction designer produces a first prototype of the SDM tool. This

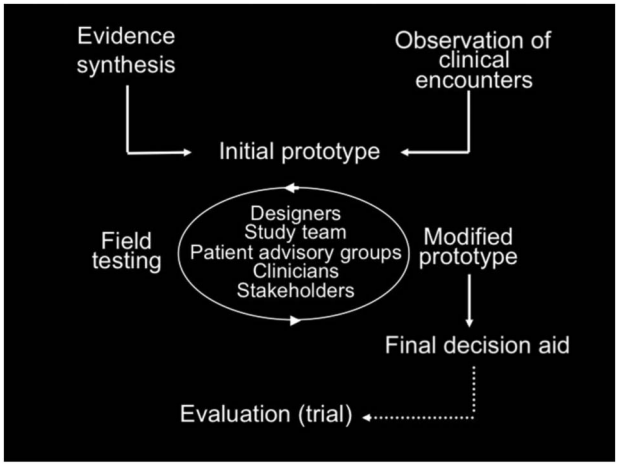

FIG 1. Design process for encounter decisions conducted by the Knowledge and Evaluation Research Unit at Mayo Clinic.

prototype pays attention to the needs in practice primarily, while seeking adherence to the International Patient Decision Aid Standards.[25]

6. Field testing: the prototype is used in consultations by oncologists and patients. Each clinician will use it in about three to four real-life clinical encounters either directly observed or video recorded. After each use of the prototype, we ask patients and clinicians about their experience and whether they recommend any changes. On the basis of observations and participant input, the developer team modifies the tool and field tests it again. Arriving at a final prototype that patients and clinicians find useful, usable, and desirable usually requires three to five iterations and about 20 or so encounters.

Two Examples of SDM Tools for Cancer Risk

The Thyroid Cancer Treatment Choice is a tool grounded in evidence that facilitates the discussion of treatment options for papillary microcarcinomas. Pilot testing has indicated that using this tool enhances the acceptance of active surveillance, suggesting that it is a viable and desirable alternative for patients who are well-informed. Following its initial implementation as a paper-based instrument, Thyroid Cancer Treatment Choice has been adapted as an electronic tool. This new version (Fig 2) permits risk stratification on the basis of age and cancer progression and can be integrated into electronic health records for individualized care. Furthermore, this updated version includes the option of ultrasound-guided percutaneous ethanol ablation for institutions that provide this form of treatment.[26]

Non–small-cell lung cancer (NSCLC) Adjuvant Choice is a tool for patients and clinicians to engage in SDM for the adjuvant treatment of resected NSCLC. Given the advances in the adjuvant treatment of NSCLC and the incorporation of immunotherapy and targeted treatments in selected patients, this tool supports the discussion for personalized options of the patients on the basis of their disease's biomarkers. The prototype was developed to include a personalized calculator of the patient's risk of dying within 5 years depicted in a 100-person pictograph on the basis of available treatments, stage, PD-L1 expression, and EGFR mutation status. It supports the discussion of the different options by depicting each treatment option's special considerations and side effects (Fig 3). The tool is undergoing field testing.

Making (CANCER) Care Fit Manifesto

In March 2021, a group of 25 individuals led by Dr Marleen Kunneman and hailing from seven countries convened to identify and deliberate on the indispensable prerequisites for establishing care that is tailored to the unique needs of each patient.[2] Their official statement states the necessity for clinicians, patient advocates, policymakers, researchers, and editors to collaborate toward promoting and facilitating initiatives that streamline the process of personalized care, in conjunction with patients and their caregivers.[27]

We contend that the principles described in the manifesto are very relevant to cancer care. In line with the Making Care Fit Manifesto, care optimized for patients with cancer must adhere to the following criteria:

1. Maximally responsive to patients' unique situation.
2. Maximally supportive of patient priorities.
3. Minimally disruptive of patient lives.
4. Minimally disruptive of patients' loved ones and social networks.

One could argue that an additional requisite is now essential—that care processes and systems be maximally disruptive of structural inequities.

A PATIENT REVOLUTION IN CANCER CARE?

Efforts to implement patient-centered care, such as SDM, however, face seemingly adverse conditions that drive toward efficiency, making it difficult to implement these practices routinely.[28]

For patient-centered care to thrive, health care organizations must foster conditions that favor care.[29] In addition to ensuring the provision of evidence-based treatments, clinicians and patients should be able to cocreate plans of care that maximally respond to the goals and priorities of each person and to their biologic and biographical situations and that are desirable, useful, and feasible in their lives. Every clinician and patient would want this, and health care organizations must ensure that they enable patient-centered care within relationships of trust not simply transactional encounters.[30] Achieving careful and kind care for all will facilitate formation, practice, and innovations in patient-centered care, including SDM as a method for cancer care.

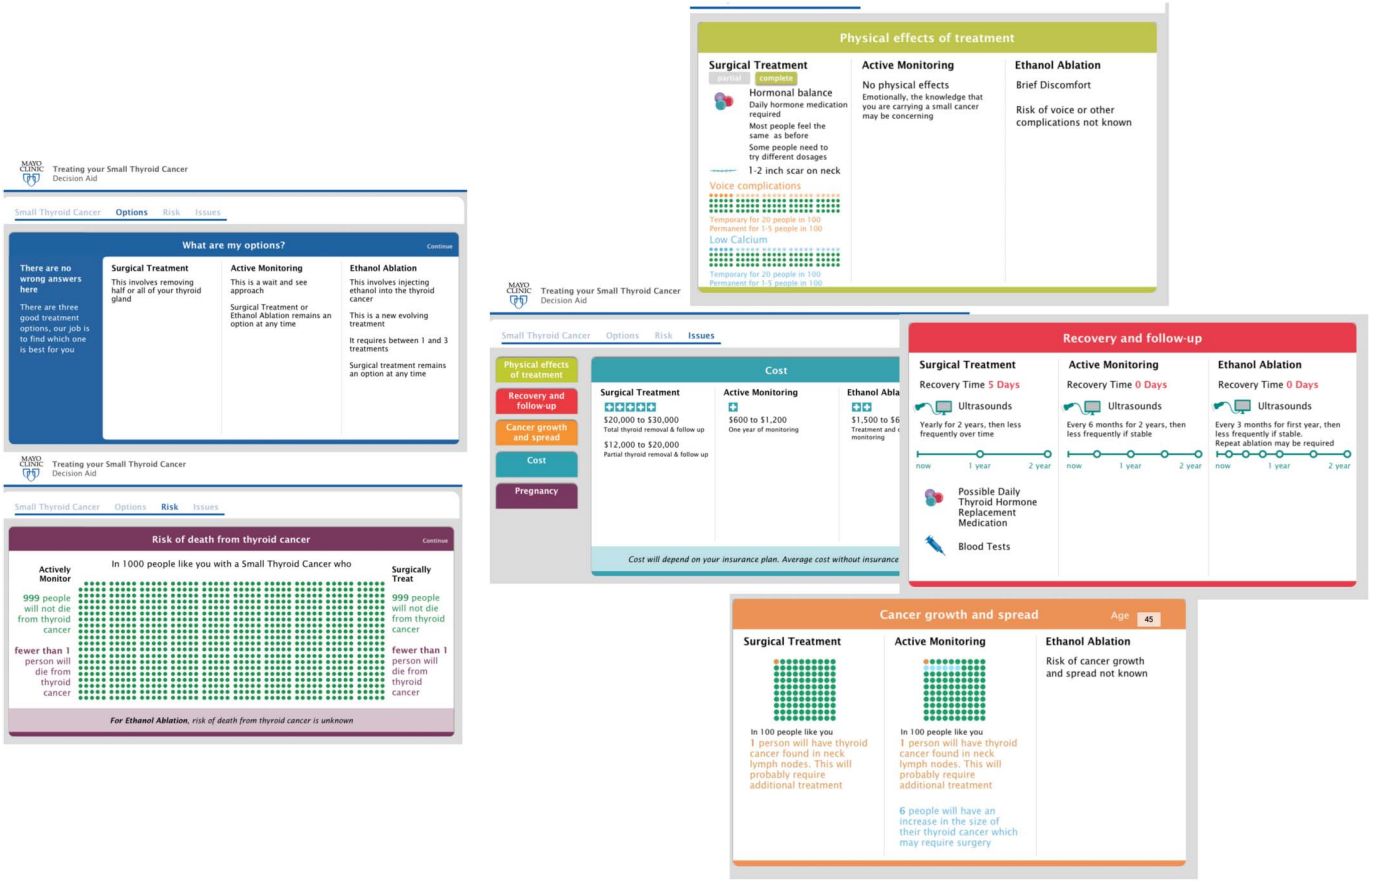

FIG 2. Screen captures of the online shared decision making tool about the treatment of patients with small thyroid cancer. Reproduced with permission. 2023 Mayo Foundation for Research and Education.

Yet, innovations to facilitate patient-centered care and SDM cannot wait for more supportive care conditions. Such innovations are in fact emerging in many cancer settings, especially within cancer genetics. Here, patients routinely undergo genetic testing, a test that can have a broad range of implications for the patient and their family, underscoring the need for SDM.

DIGITAL TOOLS TO ADVANCE SDM FOR CANCER GENETIC TESTING

Genetic testing to identify whether a patient has a hereditary cancer syndrome (HCS) represents a prime example of the importance for SDM in oncology. Nearly one in 10 patients diagnosed with cancer have an underlying HCS.[31-33] Patients with HCS have a germline gene mutation that predisposes them to develop multiple, early-onset cancers over their lifetime. Common types of HCS include hereditary breast and ovarian cancer (HBOC) syndrome because of *BRCA1/2* gene mutations and Lynch syndrome because of mutations in mismatch repair genes.[32,34,35] Females with HBOC have increased risks for multiple cancers, including 60%-80% chance of developing breast cancer and 11%-44% chance of developing ovarian cancer, whereas males have a 1%-8% risk for breast cancer and 20%-60% risk for prostate cancer.[31,34-40] Males and females with Lynch syndrome are at up to a 70% risk for colorectal cancer, 18% risk for stomach cancer, and 20% risk for small bowel, hepatobiliary tract, urinary tract, brain, and skin cancers (sebaceous neoplasms),[31,41-45] with males also having a 20% risk of prostate cancer[41-44] and females also at risk for endometrial cancer (12%-46%), breast cancer (13%), and ovarian cancer (20%).[41-44] Given these high risks, the National Comprehensive Cancer Network, ASCO, and the American Society of Breast Surgeons recommend that patients with a personal and family history of cancer undergo genetic testing to identify whether they have an underlying HCS and advocate for the importance of SDM in counseling patients for genetic testing.[46-49]

SDM is important for genetic testing because results have broad implications, including influencing current cancer treatment, changing future cancer surveillance, triggering management changes for relatives, generating complex

results, and causing psychological concerns. Oncologists offering genetic testing can address these issues during counseling, akin to counseling that they routinely undertake for diagnoses and treatments. This counseling should include an in-depth review of important educational concepts and psychosocial issues. For example, patients need to understand that identification of an HCS can lead to tailored treatment for a current cancer and targeted surveillance for future cancers. For example, a woman recently diagnosed with ovarian cancer with an underlying *BRCA1* mutation can be treated with PARP inhibitors, which can improve her survival compared with conventional treatments.[50] Patients identified to have Lynch syndrome become eligible for annual/biennial colonoscopies, beginning at age 20-25 years, in addition to consideration of prophylactic surgeries for women (eg, hysterectomy). These risk-reducing measures lead to earlier detection and prevention, reducing morbidity and mortality in this high-risk population.[51-53] For the patient's relatives, a new diagnosis of an HCS means that they become eligible for genetic testing, with potential ramifications for their own cancer treatments and surveillance.

Another point of concern is the recent transition to larger, more comprehensive genetic tests (eg, large gene panels, genome sequencing); these have increased the likelihood that uncertain results and secondary findings will be revealed, both of which can contribute to challenges in the patients' cancer management and surveillance. Patients should also be informed about the possibility of psychological harms triggered by the genetic testing process or results (eg, distress associated with new cancers, uncertain findings, anxiety and burden around sharing results, guilt of passing on an HCS to children, etc). Adding on to these challenges is the fact that there is often no clear right or wrong decision about whether to pursue genetic testing; the decision is often informed by the patients' values and preferences. As such, it is imperative that patients and their clinicians undertake in SDM, a process that ensures that patients understand all their options and that they incorporate their values into their decision making, to choose the option that is most consistent with their preferences and goals.[54-56]

Despite the increasing importance of SDM, the ability to achieve it has become more challenging as the quality and extent of patient-clinician consultations have decreased over time. Within oncology, this decline can be attributed to multiple factors including the shortage of health care professionals, increased demand for cancer services because of an aging population, and the increasing *industrialization of health care*.[28,57,58] The latter describes the application of management and improvement approaches used in the manufacturing industry and applied to health care delivery.[28] Although designed to enhance standardization, reliability, and efficiency, the industrialization of health care has also exacerbated burnout among clinicians and exhaustion in patients.[28] Moreover, the emergence of the COVID-19

pandemic in early 2020 further exacerbated resource constraints in oncology. The pandemic also transitioned most medical appointments to virtual settings, reducing face-to-face encounters between providers and their patients. Engaging in SDM has become even more challenging with these constraints.[28] As such, new and innovative models of SDM are needed within oncology.

Digital tools are one strategy that can facilitate SDM in patient-clinician consultations and move away from industrialization of health care in oncology.[28] There is evidence from the literature to support this; a recent systematic review found that digital tools can support the many facets of SDM, including increasing patient knowledge, improving psychosocial well-being and engagement, and facilitating decision making.[59] For clinicians, the review found that digital tools provide efficiencies by reducing the time needed with patients and enhancing workflow (eg, less time needed to prep charts).

One example of a digital platform that can support patients and oncologists in delivering genetic testing and SDM is the Genetics Adviser.[60,61] The Adviser is an interactive, patient-facing, digital platform that supports the fundamentals of SDM—by providing both education and psychosocial support at all points in the patients' cancer journey. The Adviser includes interactive educational module that provides in-depth, patient-targeted information. The platform also encompasses values clarification exercises that can help patients explore their values and preferences. Even after patients finish the education modules and values exercises, they have the option to return to the platform at any time, review any materials they completed, and access additional support resources. They can also generate a printable summary that can be easily shared with their circle of care and support (Fig 4). All these steps can be completed at the patients' pace—allowing them to involve their relatives and larger support system in the decision making process. The Adviser's modules and exercises can easily be customized to the oncologists' and patients' needs. They can be used to support patients undergoing genetic testing in mainstreaming practices, patients undergoing rapid genetic testing for treatment purposes, and patients having their tumor profiled, which could reveal germline findings. Moreover, for patients undergoing genetic testing during cancer treatment, the platform provides a flexible resource that can be accessed at any time using multiple modalities (eg, smartphone, desktop, etc) and within any setting (eg, home, work, clinic).

There is considerable evidence that supports the effectiveness of the Genetics Adviser platform in advancing SDM in the oncology setting. For example, one qualitative study found that the Adviser promoted informed dialogue, facilitated preference-sensitive deliberation, and deepened personalization of decisions of patients with cancer.[62] These three functions represent fundamental elements of patient-centered care[63,64] and provide evidence that the platform can facilitate SDM.[65] In addition to facilitating SDM, digital tools like the Genetics Adviser are in line with principles of the *Open Notes Movement*.[66] The real-time sharing of genetic test results through a secure portal reduces uncertainty and promotes transparency. Furthermore, the inclusion of communication through the portal enables asynchronous interaction between the clinician and the patient, reducing the risk of anxiety as the patient awaits their scheduled appointments.[66]

Digital tools such as the Genetics Adviser can educate and empower patients with cancer, giving them agency in their cancer journey. Patients can use the platform to prepare themselves before the initial consultation and then come to a subsequent clinic appointment with their oncologist better prepared and empowered to engage in SDM. As evidence from a recent trial revealed,[67] this will reduce the consultation time that patients need with the health care providers. Therefore, the platform provides an opportunity to have an efficient appointment, reserving the precious and limited clinic time to focus on each patient's unique concerns. Instead of receiving information for the first time at the appointment, patients are coming to the first consultation empowered, having already had a chance to digest the medical information, consult with their circle of care and family, and come prepared with questions. Since the patient has already reviewed the technical and background information, clinicians can focus the time on the patients' specific questions and explore preferences and values to help patients make informed decisions. This indeed was observed in a recent qualitative study, which found that the Genetics Advisor platform increased the degree of deliberation and verbal engagement between patients with cancer and the clinician.[62] This provided the clinician with opportunities to respond to the unique perspectives and experiences of each patient, including clarifying misunderstandings and highlighting personal values, consistent with patient-centered care. Therefore, digital tools can make it easy for oncologists to achieve true SDM with their patients.

Digital tools and other SDM innovations are also facilitating a paradigm shift toward the cocreation of plans of care as a collaborative method to uncover, discover, or invent a response to each patient's problematic situation. This joint work must address the situation as understood by the patient and the clinician, must draw from the best research evidence and from the experience and expertise of the patient and the clinician, and must consider health care resources and the resources that the patient and their caregivers can mobilize to implement the care plan effectively and safely. This places the patient not as a party who must be engaged, involved, or

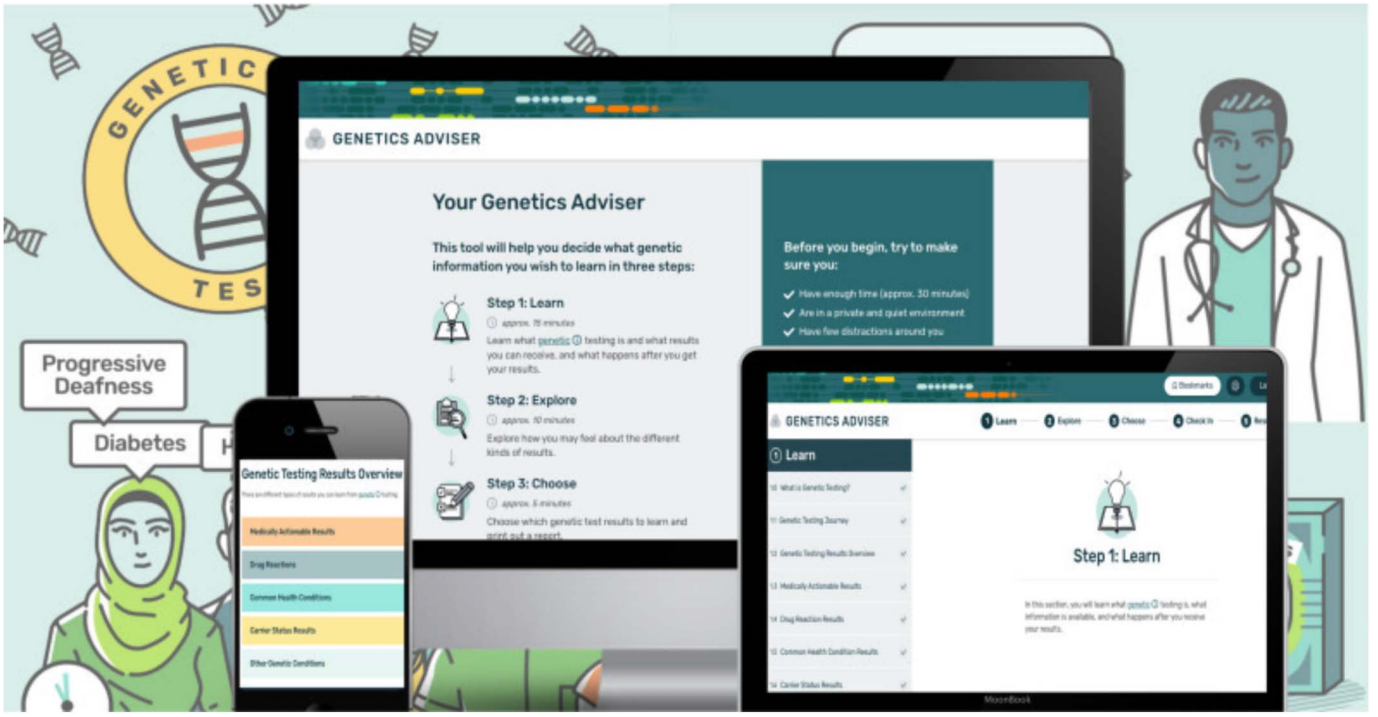

FIG 4. The Genetics Adviser, delivering pretest counseling, waiting period support, and result disclosure via all mobile applications such as smartphones and tablets or computer/desktop applications. Source: PMID: 35487723 with permission.

empowered, but who takes a practical role as an integral codeveloper of plans of care.

SDM FROM A PATIENT PERSPECTIVE

The paradigm guiding interactions between the clinician and the patient is undergoing a sea change. Under the long-prevalent model of paternalism, the doctor was the predominant—if not exclusive!—source of judgment as to the proper course of medical action. But, increasingly, the patient's embodied perspective is being considered when making clinical choices, a shift that respects both an ethical emphasis on autonomy and a pragmatic need to individualize care. Sometimes, SDM is contingent on factors that are known only to the patient and beyond the discernment of quantitative tools at the diagnostician's disposal, obligating an information transfer back and forth for authentic shared governance[68] (M.A.L. is an oncologist living with a hereditary cancer. He has shared his perspective as a patient here: The ASCO Post[69]).

However, it must be acknowledged that even SDM is a term encompassing multiple approaches in need of careful differentiation. In the *informative model*, the clinician provides the patient with all relevant information without recommending a course of action. In the *interpretive model*, the clinician aims to elucidate the patient's values and desires and to help the patient select the available medical intervention that is most congruent with their principles and goals. Although both models require an explanation beyond the dictums of paternalism, the second is a more open exchange of ideas, a bidirectional discourse that does not presuppose an outcome and calls on both sides to adapt to what they are hearing.[70,71] This model is particularly well-suited to decisions in which there is more than one medically reasonable option, and the best plan hinges on patient goals, priorities, values, and preferences.

Implicitly or explicitly, the interpretive model acknowledges the patient as the ultimate stakeholder in their medical outcome. Although fiduciary responsibility is a noble lodestar for minimizing any interference from the physician's own self-interest, even the most empathetic of clinicians does not experience cancer in the same way as those entrusted to their care. Whether the relative abstractions of quality of life or the most clear-cut end point of mortality, it is the patients' own fitness and longevity that are threatened by disease (and, in some cases of iatrogenic harm, its treatment!). As such, they are appropriately positioned as the arbiters *par excellence* as to which metrics matter and which risk/benefit ratios are acceptable, including the ever-present choice of forgoing cancer-directed therapy altogether.

Adding to this modernization of the doctor-patient relationship is the surfeit of digital resources made available to

the public in the information age. Unsurprisingly, among patients with online access, 97% will use the Internet on diagnosis to find information about cancer, with 94% searching on Google. However, the ready yield of results from such a massive search engine carries important caveats; although Google can provide relatively accurate information about etiology and symptoms, it is far less reliable in its descriptions of treatment and prognosis. Efforts to use wording commensurate with average scientific literacy, for example, plain language summaries, are admirable in their inclusivity but carry tradeoffs between reliability and readability. Patients with rarer cancer are particularly vulnerable to the surfacing of misinformation, and even more common diagnoses still require shrewdness about the algorithmic ordering of recommendations for treatment; for instance, searches about specific medications will lead to pharmaceutical websites approximately 20% of the time introducing at least the specter of commercial bias.[72-76]

All told, such patient-initiated digital engagement is both entirely understandable and vulnerable to exploitation or at least misinterpretation. Medical professionals can provide critical assessment of what patients discover during their own online inquiries, vetting search results and separating fact from fiction, meritorious studies from pseudoscience. The once-fallow time between visits now becomes a fertile opportunity for the patient's own preparation asynchronous from their doctor's; they can arrive at their appointments with questions shaped by their independent reading and learn which resources are validated for further self-directed research.[66]

Another potential opportunity for misunderstanding arises through the direct access of laypeople to their *own* test results through patient-facing portals. With the commendable intent of empowering patients, the Open Notes movement embraces transparency and timeliness in the sharing of medical documentation.[77-79] The near-instantaneous delivery of results through secure channels ideally reduces uncertainty and decouples the reporting of a diagnostic test from an in-person visit. Surveys have revealed that many patients taking advantage of this technology feel as if they are more active participants in their treatment when granted this access. They are also more likely to retain the content of in-visit discussions with their doctor, as opposed to purely verbal recall.[80,81] However, if a patient receives the results of a test when an ordering physician is unavailable to help them interpret it, the temporal mismatch may engender more apprehension than if the doctor was explaining the clinical meaning in proper context.[82]

This is especially true of genetic results, which can have life- and family-altering consequences while also being freighted with diagnostic uncertainty, for example, variants of unknown significance. Even the fundamental bifurcation of mutations into somatic and germline defects may be overlooked, with the concern that the former could be extrapolated to a presumption of a hereditary risk. As Martin *et al* frame it, "despite the well-understood benefits of biomarker and genetic testing in precision medicine, uptake remains low… Patients report having limited familiarity with testing terminology and may not be able to accurately explain testing's role in treatment decisions. Patient confusion and lack of understanding is exacerbated by a multiplicity of overlapping terms used in communicating about testing."[83] As a corrective, they propose "democratizing comprehension about precision oncology testing through intentional use of plain language and common umbrella terminology by oncology health care providers and others in the oncology ecosystem may help improve understanding and communication and facilitate shared decision-making about the role of appropriate testing in treatment decisions and other aspects of oncology care."

Outside of cancer medicine, Huntington's disease is often cited as an incisive exemplar of genomic foreknowledge's double-edged sword. The subject's awareness of being the gene carrier of an inexorably progressive and uniformly fatal neurodegenerative disorder can induce intrusive emotions, denial-avoidance behavior, and pessimistic expectancies of the future and adjustment problems.[84] Within oncology, several germline mutations require relatively major surgical interventions early in life to mitigate the risk of oncogenesis. Patients with the CDH1 mutation might have to undergo prophylactic total gastrectomy by the fourth decade, whereas patients with familial adenomatous polyposis have often been considered for colectomy by around the same age. Parents of children with multiple endocrine neoplasia type 2 can even face the wrenching prospect of prophylactic thyroidectomy by their infant's first birthday to avoid medullary thyroid carcinoma arising from proto-oncogenic RET codons 883, 918, or 922.[85,86]

But even the advanced awareness of less lethal predispositions before they become phenotypically evident can pose threats that are harder to quantify. Some medical ethicists posit that contemporary predictive biomedicine has created a *sui generis* diagnostic category: the prepatient. Such persons risk being perceived as ill before they are diseased. As a transitive responsibility, the moral burden of conveying a bad prognosis shifts to the kin, who are then obliged to make decisions about when and how to share or withhold genetic information with other potentially presymptomatic relatives.[87,88]

CONCLUSION

SDM is a method of care on the basis of conversations conducted to arrive at a cocreated plan of care that addresses the problematic situation of each patient. Unhurried

conversations, SDM tools, and collaborative deliberation methods are essential to coproduce care plans with active participation of patients and clinicians. The experience of patients in contributing to care that fits requires access to trustworthy information, experience, and expertise, both within and between clinical encounters. Health care systems that favor the processing of people rather than the care of patients are hostile to methods of patient-centered care, such as SDM, and must be radically reformed if SDM is to become routinized in care.

Patient-Reported Outcomes, Digital Health, and the Quest to Improve Health Equity

Joshua C. Pritchett, MD[1,2,3]; Debra Patt, MD, PhD, MBA[4]; Gita Thanarajasingam, MD[1]; Anne Schuster, PhD, MHS[5]; and Claire Snyder, PhD, MHS[6,7,8]

Overview

The theme of the 2023 American Society of Clinical Oncology Annual Meeting is Partnering With Patients: The Cornerstone of Cancer Care and Research. As we aim to partner with patients to improve their health care, digital tools have the potential to enhance patient-centered cancer care and make clinical research more accessible and generalizable. Using electronic patient-reported outcomes (ePROs) to collect patients' reports of symptoms, functioning, and well-being facilitates patient-clinician communication and improves care and outcomes. Early studies suggest that racial and ethnic minority populations, older patients, and patients with less education may benefit even more from ePRO implementation. Clinical practices looking to implement ePROs can refer to the resources of the PROTEUS Consortium (Patient-Reported Outcomes Tools: Engaging Users & Stakeholders). Beyond ePROs, in response to the COVID-19 pandemic, cancer practices have rapidly adopted other digital tools (eg, telemedicine, remote patient monitoring). As implementation grows, we must be aware of the limitations of these tools and implement them in ways to promote optimal function, access, and ease of use. Infrastructure, patient, provider, and system-level barriers need to be addressed. Partnerships across all levels can inform development and implementation of digital tools to meet the needs of diverse groups. In this article, we describe how we use ePROs and other digital health tools in cancer care, how digital tools can expand access to and generalizability of oncology care and research, and prospects for broader implementation and use.

INTRODUCTION

The theme of the 2023 American Society of Clinical Oncology (ASCO) Annual Meeting is Partnering With Patients: The Cornerstone of Cancer Care and Research. This theme serves as a call to deepen our commitment to connect with the communities we serve. As we aim to partner with patients to improve their health care, patient-reported outcomes (PROs) offer a systematic approach to incorporate the patient's perspective in oncology care and innovation. PROs are patients' own reports of how they feel, function, live their lives, and survive.[1,2] They include outcomes such as symptoms, functional status, and health-related quality of life and are assessed with standardized validated questionnaires reported directly by the patient without interpretation from a clinician or anyone else. To our knowledge, one of the most well-established and increasingly prevalent examples of digital implementation in cancer care to date is electronic patient-reported outcomes (ePROs). Beyond ePROs, digital tools are a growing part of care delivery, contributing to collaboration between patients and their clinicians by supporting communication, health literacy, measurement, timely symptom management, and research needs.

In response to the COVID-19 pandemic, cancer practices have rapidly adopted and expanded ePROs, telemedicine approaches, remote patient monitoring, and other digital strategies to meet the unprecedented needs of the moment for their patients. As implementation grows, we must be aware of the limitations of these tools and implement them in ways to promote optimal function, access, and ease of use. In this article, we describe how we use ePROs and other digital health tools in cancer care, how digital tools can expand access to and generalizability of oncology care and research in the US, and prospects for broader implementation and use.

HOW DO WE USE DIGITAL HEALTH TO IMPLEMENT PROs IN CANCER CARE?

A key aspect of partnering with patients is ensuring that their perspectives are directly incorporated in their care journey. Having patients complete questionnaires about their symptoms, functioning, and well-being—and using that data to inform that patient's own care—promotes patient-centeredness. Benefits include improved communication between patients, physicians, and other members of the care team,[3-6] which can help them monitor treatment response and detect problems.[6-8] Integrating PROs with

Author affiliations and support information (if applicable) appear at the end of this article.

Accepted on May 5, 2023 and published at ascopubs.org on June 8, 2023: DOI https://doi.org/10.1200/EDBK_390678

PRACTICAL APPLICATIONS

- Digital tools have the potential to enhance patient-centered cancer care and make clinical research more accessible and generalizable.
- Electronic patient-reported outcomes (ePROs) have the potential to improve care and outcomes, with some evidence suggesting particular benefits among racial and ethnic minority populations, older patients, and patients with less education. Resources to aid practices in implementing ePROs are available from the PROTEUS Consortium (Patient-Reported Outcomes Tools: Engaging Users & Stakeholders).
- Beyond ePROs, digital tools such as patient portals, telemedicine, remote patient monitoring, and hospital at home can enhance patient care; electronic consent can facilitate enhanced enrollment and participation in research.
- Barriers to digital implementation at the infrastructure, patient, provider, and system-level need to be addressed. Partnerships across levels can inform development and implementation of digital tools to meet the needs of diverse groups.
- When implemented effectively, digital tools can narrow, rather than widen, health disparities.

care pathways reduces the time to symptom management and improves patient outcomes.[9,10] As our understanding of how best to incorporate PROs in clinical practice has improved, we have increasingly seen beneficial impacts on patients' functional status, quality of life, overall care management, and satisfaction with care.[3,5,10-16] Recent studies have even demonstrated improved survival.[10,12] In the United States, ePRO inclusion in the Centers for Medicare and Medicaid Innovation's alternative payment model pilot, the Enhancing Oncology Model, is a sign that ePRO implementation should be a mainstay of high-quality and transformational cancer care and will likely foster broader adoption.[9]

Some early indications suggest that using PROs in clinical practice benefits vulnerable populations even more. Basch et al randomly assigned 766 patients receiving routine outpatient chemotherapy for advanced solid tumors at Memorial Sloan Kettering Cancer Center to symptom reporting or to usual care (symptom monitoring at the discretion of clinicians).[11,17] Patients in the intervention group had better health-related quality of life, remained on chemotherapy longer, had fewer emergency department visits, and lived longer. Preplanned subgroup analyses on the basis of patients' level of computer experience showed that these benefits were even greater in the computer-inexperienced subgroup, including for emergency department visits, hospitalizations, and overall and quality-adjusted survival. Notably, computer-inexperienced patients were more likely to be older, Black, and have less education. In another example, planned exploratory analyses of a randomized controlled trial conducted at Johns Hopkins examining different PRO questionnaires for use in clinical practice found a trend toward patients from minority racial groups, with less education, or less computer usage reporting greater benefit from completing PRO questionnaires as part of their routine care.[18]

Opportunities and Challenges of ePRO Systems

Advances in technology have increased the feasibility of incorporating PROs in routine care.[19] PRO measures have to be completed by the patient, scored, and then, for maximal benefit, reported to the clinical team—ideally graphically and incorporating other clinical information (eg, previous scores on the measure along with dates of various clinical interventions). Historically, manual (paper) questionnaire completion, scoring, and reporting limited the incorporation of real-time PRO data during clinical encounters. The increased availability of ePRO systems that enable electronic questionnaire completion (in-clinic, remotely via the Internet, or both) as well as automatic scoring and reporting, has substantially expanded the scalability and use of PROs in routine clinical care.

For example, a 2014 review identified 33 unique ePRO systems for use in cancer care[20]; in a 2019 review, also cancer-focused, the number of systems identified had increased to 41.[21] More recently, several electronic health record (EHR) systems have added built-in functionality for PRO collection and reporting. A 2020 review found that ePRO systems were associated with the following advantages: lower costs, better data quality, equal or faster time to complete, lower administrative burden, and being generally preferred over paper forms.[22] However, increased use of electronic reporting systems runs the risk of inadvertently excluding vulnerable populations with less ability to use or access technology.[22] Although a recent review article found that PRO implementation is generally feasible and acceptable in the care of diverse and underrepresented patient populations (US only and not specific to electronic reporting or to cancer), it also documented disparities in PRO completion among racial and ethnic minority groups; patients who speak Spanish; patients with low income, employment status, education, and health literacy; and older populations.[23]

One of the challenges in effective patient-centered implementation of PROs relates to the mode of administration. In

a randomized clinical trial across 52 US-based community oncology practices, over a third (35%) of participants chose to complete their PRO questionnaires via an automated telephone system (*v* via computer); the investigators had anticipated only 10%-15% would choose the telephone option.[24] Similarly, Griffin et al found key demographic differences in 15,181 unique patients with cancer asked to complete PROs via the EHR patient portal, an automated telephone system, or in-clinic tablet: Patients who responded only using the telephone system were more likely to be older than 70 years or disabled.[25] The nearly 18% of patients who did not respond using any mode were more likely to be of non-White race and have a high school education or less. The data from these studies demonstrate the importance and difficulty of designing electronic PRO interventions that are widely inclusive and readily accessible to all patients.[26]

Key Tools to Support the Use of PROs in Clinical Practice

There are many topics that require consideration when implementing PROs as part of routine care, including for diverse populations. A number of tools and resources have been developed to support these efforts (Table 1).

The User's Guide to Implementing PROs in Clinical Practice was developed by the International Society for Quality of Life Research (ISOQOL).[27,28] This User's Guide walks step-by-step through the process of implementing PROs in clinical practice, starting with delineating the goals for the intervention, then determining which questionnaires are going to be completed by which patients at what frequency using which mode of administration, and finally defining approaches for reporting the results, aiding interpretation of the scores, and facilitating actions to address issues that require clinical attention. For each step in the process, the User's Guide does not recommend one right approach but rather offers a range of options with their relative advantages, disadvantages, and resource requirements. In this way, users can determine which approach fits best within their context. A companion to the User's Guide, published in 2018, uses real-world case studies to describe operational issues involved in using PROs in clinical care.[29]

An increasingly necessary consideration when implementing PROs into clinical practice relates to the integration of PRO data with EHRs. To support integration, a Users' Guide specifically focused on the considerations of PRO-EHR integration was published in 2017.[30,31] Similar to the ISOQOL tool, the PRO-EHR Users' Guide walks step-by-step through the process of PRO-EHR integration and offers a range of options along with relative advantages and disadvantages. It complements the ISOQOL User's Guide by focusing specifically on EHR integration considerations.

Another issue related to the use of PROs in clinical practice is the best way to graphically display the PRO scores so that patients and clinicians can easily and accurately interpret their meaning. A multiphase international research study explored approaches for displaying patients' PRO scores graphically to identify the formats that are interpreted most accurately and rated clearest.[32-34] The research study results then informed the development of stakeholder-engaged, evidence-driven recommendations for how to display PRO data to promote understanding and use.[35]

Two other important aspects of using PROs in clinical practice are aiding interpretation of the PRO scores and facilitating clinical responses to issues identified through the PRO assessments. To address these issues, the journal *Medical Care* published a supplement series of papers that provide a methodological toolkit for interpreting and acting on PRO scores.[36] The first six papers in the series describe different approaches for aiding interpretation of PRO scores, including quantitative, qualitative, and psychometric approaches.[37-42] The following eight papers describe different ePRO systems from multiple countries and the approaches they use to aid PRO score interpretation and/or to facilitate action in response to the PRO results.[43-50] As such, the *Medical Care* supplement offers a range of methods that users can apply in their own PRO implementations.

Finally, the ePROs in Clinical Care Toolkit was developed to help health care systems implement ePRO data in clinical care delivery.[51] It builds on several of the resources described above, including the ISOQOL and PRO-EHR Users' Guides, but is unique in that it focuses primarily on the health system perspective, specifically governance, integration, and reporting. Similar to the other resources, it does not provide a prescription for addressing these issues but rather presents a range of strategies that have been used in other health systems. The website also includes interactive tools to support translation of the guidelines into practice.

The above tools are being implemented and disseminated through the international PROTEUS (Patient-Reported Outcomes Tools: Engaging Users & Stakeholders) Consortium.[52] PROTEUS helps navigate the use of PROs in clinical trials and clinical practice by engaging with key stakeholder groups to disseminate and implement relevant tools and resources. On the basis of input from the 53 patient, clinician, research, health system, industry, policy, government, and regulatory groups in the Consortium, a new tool is currently under development to synthesize and consolidate the information from the five separate tools to create a single, unified resource. This new tool is expected to be available on the PROTEUS website in Spring 2023.

Ensuring Inclusion of Vulnerable and Underserved Populations in PRO Systems

As noted above, the use of PROs to inform the monitoring and management of patients with cancer might have particular value for vulnerable and underserved populations,

TABLE 1. Summary of Key Tools to Support the Use of PROs in Clinical Practice

Tool	Purpose	Content Covered
User's Guide to Implementing Patient-Reported Outcomes Assessment in Clinical Practice	To outline the steps in implementing PRO assessment as part of routine care and, for each step, provide a range of options and their relative advantages and disadvantages	Identifying the goals for collecting PROs in clinical practice Selecting the patients, setting, and timing of assessments Determining which questionnaire(s) to use Choosing a mode for administering and scoring the questionnaire Designing processes for reporting results Identifying aids to facilitate score interpretation Developing strategies for responding to issues identified by the questionnaires Evaluating the impact of the PRO intervention on the practice
Users' Guide to Integrating Patient-Reported Outcomes in Electronic Health Records	To outline the steps in integrating PRO assessment and reporting in electronic health records and, for each step, provide a range of options and their relative advantages and disadvantages	Strategy for linkage Governance Training and engaging Patients/populations Outcomes Measure evaluation Questionnaire administration Score display Acting on results Data pooling Ethical/legal issues
Recommendations for graphically displaying patient-reported outcomes data	To report stakeholder-driven, evidence-based recommendations for graphically displaying PRO data to promote understanding and use	Recommends the consistent use of line graphs of scores over time Addresses confusion associated with differing directionality in scoring (ie, whether higher scores are better or worse) Suggests approaches to convey score meaning (eg, what is mild, moderate, severe) Describes how to identify possibly concerning results
A PRO-cision Medicine Toolkit to Address the Challenges of Personalizing Cancer Care Using Patient-Reported Outcomes	To describe a range of methods to address the issues of (1) aiding interpretation of PRO scores and (2) acting on PRO results	Quantitative, qualitative, and modern measurement theory-based approaches for identifying cutpoints (eg, mild, moderate, severe) How reference values, aggregated data, and group-level PRO metrics may aid interpretation Descriptions of how eight PRO systems aid interpretation of, and promote action based on, PRO results

TABLE 1. Summary of Key Tools to Support the Use of PROs in Clinical Practice (Continued)

Tool	Purpose	Content Covered
ePROs in Clinical Care Toolkit	To help health care systems implement ePRO data in clinical care delivery	Governance to align ePROs with health system goals Align goals for ePRO use with information technology infrastructure Establish an ePRO governance structure Identify governance activities that guide practice Disseminate best practices for use and management Integration to clarify how data will be accessed and support care Design workflows for easy data capture Leverage health information technology to encourage maximum ePRO use Engage users in ePRO adoption and use Encourage continuous learning during implementation Reporting to display most useful statistical presentation Provide longitudinal PRO information Provide comparative PRO information Augment PRO data with contextual information Automate to improve ePRO workflow Customize to enhance usability Include drill down and up capacity Provide means to filter PRO data Integrate PRO and clinical data platforms Accommodate multiple platforms Visually enhance key information Provide simple and familiar graphs Organize display of multiple visualizations Model clinical use of ePRO reports

Abbreviations: ePRO, electronic PRO; PRO, patient-reported outcome.

but these populations might also require special attention to ensure that PRO systems are designed to meet their needs. To address these issues, the PROTEUS Consortium is forming an Advisory Group for Patient-Reported Outcome Implementation in Vulnerable and Underserved Populations, focused on oncology care in the United States. The aims of this Advisory Group are to (1) improve our understanding of the facilitators of and barriers to implementing routine PRO assessments in institutions caring for vulnerable and underserved populations and (2) build capacity for PRO implementation to improve care for patients with cancer who are vulnerable or underserved. The Advisory Group will include a range of perspectives, reflecting expertise both in PRO implementation and in care for vulnerable and underserved populations. On the basis of the discussions, a strategy document will be prepared to outline action steps that PROTEUS and other organizations can take to promote the inclusion of vulnerable and underserved populations in PRO interventions.

EXPANDING ACCESS TO AND GENERALIZABILITY OF ONCOLOGY RESEARCH AND CARE WITH DIGITAL HEALTH TOOLS IN THE UNITED STATES

Although ePRO implementation in routine oncologic care offers a clear opportunity to partner with patients using technology, additional digital tools can further facilitate remote care monitoring and decentralization of both research and care (Fig 1). This section will focus on implementation in the United Sates, though it should be noted that expanding access to and generalizability of oncology research and care, particularly in low- and middle-income countries, is a global priority and challenge, warranting dedicated efforts and international collaboration. At present, clinical trials in the United Sates are not available or accessible to many patients with cancer and thus the real-world applicability of trial results is limited.[53] Digital health tools provide an opportunity to facilitate health equity in cancer care by expanding the reach of high-quality oncologic care and research to patients and by facilitating generation of data that better represents the population. However, as described earlier with ePROs, these technologies have the potential to both narrow and widen a digital divide in cancer care and must be adopted thoughtfully to achieve key goals in health equity, access to care, and representation of a real-world population (Fig 2).

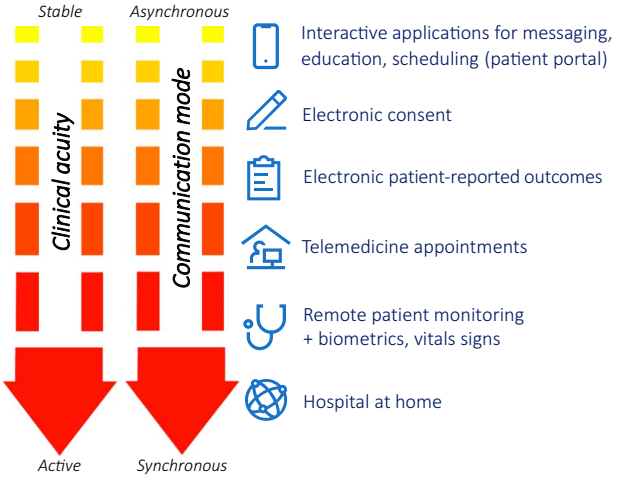

FIG 1. Examples of digital tools being implemented across the continuum of cancer care and research.

Opportunities Provided by Digital Health Tools in Oncology Research and Care

The historical underrepresentation of many Americans in cancer clinical trials is reflective of deep structural barriers to high-quality cancer care. Despite representing 13.4% and 18.5% of all patients with cancer, <6% of cancer clinical trial participants are Black or Hispanic, respectively.[54-57] Although populations older than 70 years comprise more than 42% of the US population with cancer, only 25% of participants in cancer clinical trials are older than 70 years.[53,58-60] Although 20% of the US population lives and works in rural areas, only 3% of oncology practices provide local care and clinical trial opportunities in these areas, and it is well known that clinical trial involvement and travel burden have a direct impact on clinical outcomes for rural patients with cancer.[55,61-64]

While efforts to improve these disparities are ongoing, the unprecedented growth of digital health tools as a result of the COVID-19 pandemic has provided a unique opportunity for accelerated progress. In the research setting, digital health technologies have the potential to facilitate clinical trials with broader reach, generating data more representative of the population.

For example, the deployment of remote consent and follow-up is a strategy adopted by many trials to sustain access and accrual during the height of the COVID-19 pandemic.[65,66] This remains a viable approach, enabling ongoing decentralization of therapeutic trials for patients who may not otherwise be able to participate. Furthermore, remote consent and decentralization can facilitate pragmatic outcome studies with a focus on enrolling real-world cohorts. In the ongoing study Integrating 4 Measures to Assess Physical Function in Cancer Patients (In4M),[67] the US Food and Drug Administration and academic collaborators from Mayo Clinic and Yale University aim to capture multimodal data on physical function in patients with cancer undergoing chemotherapy using patient reports, wearable sensor data, clinician-reported Eastern Cooperative Oncology Group performance status, and a 6-minute walk test. Data on symptomatic and laboratory adverse events, hospitalizations, acute care visits, dose modifications, and quality of life

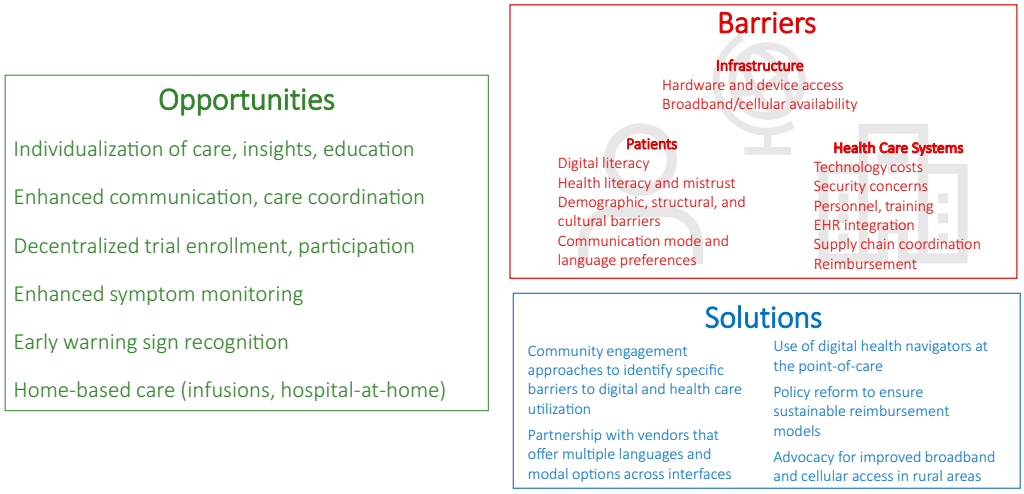

FIG 2. Implementation of digital tools across cancer care and research: opportunities, barriers, and solutions. EHR, electronic health record.

are also collected. The study is available to patients treated at their home sites, who are followed remotely by the study team and a data-aggregating digital platform. Efforts like this—which integrate digitally captured ePROs and biometrics in a decentralized fashion—represent a new model to help researchers and clinicians better assess cancer treatment tolerability in real-world populations in real time.

In the practice setting, use of digital health technologies has expanded access as well. Given the significant patient-related costs required for rural patients to receive in-person cancer care (greater travel distances, additional lodging, etc), telehealth services had long been considered a potential solution.[68,69] However, this approach had minimal adoption until 2020, when the national public health emergency (PHE) declaration and executive shelter-in-place orders propelled cancer practices to rapidly implement nontraditional models of care delivery.[69-73] Since 2020, with improved reimbursement and loosened restrictions provided through the PHE declaration, US cancer practices have been able to sustain rapid adoption of telemedicine services.[69,72,73] Beyond the initial pandemic response, a study presented at ASCO 2022 demonstrated ongoing growth and integration of telemedicine across a major multiregional cancer practice.[72,73] Furthermore, this study demonstrated that increased telehealth visit utilization did not result in duplicative care or compromise patient satisfaction with care.[73] In another study presented at ASCO 2022, the experience of implementing digital tools across a large community oncology practice was reported. In more than 600,000 episodes of digital tool use, engagement was high across various demographic parameters—age, sex, ethnicity, and rural versus urban.[74]

Beyond telemedicine, ePROs are being used in conjunction with prespecified nurse-driven clinical management algorithms to further streamline and individualize care. In the CAPRI trial, ePRO-driven nurse navigator support was shown to increase adherence to oral anticancer agents while also decreasing treatment-related toxicities and total hospital days.[75] The incorporation of devices capable of uploading vital signs and biometric data for real-time review by care teams has further enabled the use of remote patient monitoring (RPM) programs in acute and subacute care settings. The Mayo Clinic DEFeNDR program provides patients with a kit of preconnected, cellular-enabled devices to upload vital signs and symptoms directly integrated with the EHR, facilitating real-time ambulatory monitoring and management of febrile neutropenia as an alternative to hospital-based care (Pritchett et al, ASCO 2023). Similar RPM programs are being used to facilitate outpatient monitoring and management of patients receiving CAR T-cell therapy[76] and have been shown to reduce hospitalizations and acute care utilization in cancer patients with COVID-19.[77] Further still, digital advancements across multidisciplinary care ecosystems have enabled institutions to shift administration of some chemotherapy infusions to the home environment, as well as provide complex, inpatient-level care in the ambulatory setting. Penn Medicine's Cancer Care at Home (CC@H) program has demonstrated the safety, feasibility, and scalability of this approach,[78] and Huntsman Cancer Institute's Huntsman at Home model has shown the feasibility of this model to overcome geographic disparities among rural populations with cancer.[79]

Challenges of Digital Health Tools in Oncology Research and Care

Although digital tools have the potential to make research more accessible, generate research findings that are more representative of real-world populations, and enhance individual patient care, they also have the potential to exacerbate disparities among the very populations they are intended to serve.[80] Ensuring that digital tools resolve disparities in care requires attention to multilevel factors that influence whether patients can access and use them.

These factors span infrastructural issues, patient-specific considerations, and provider and health care system limitations (Fig 2).

In terms of infrastructure, access to adequate hardware and Internet connectivity represent two important barriers. In a 2020 study, 41.4% of Medicare beneficiaries did not have a computer with high-speed Internet connection at home, 40.9% lacked a smartphone with wireless capability, and 26.3% had neither (this was even higher for Black or Latinx individuals, those with lower income, high school education or less, patients on Medicaid, and those who reported having a disability).[81] Differences in digital care utilization such as patient portal use have been shown to be significantly affected by Internet access,[82] and the availability of high speed broadband and/or cellular-based Internet access in many rural areas represents a major barrier.[83,84] Among rural populations with cancer, video visit utilization rates have been shown to be significantly lower and phone visit rates significantly higher than patients from nonrural residences.[73] Although the comparatively high rate of phone visit utilization indicates a willingness of rural patients to participate in telehealth overall, the disparity in video visit utilization compels a need for further studies to examine barriers to video visit use among rural populations. Ultimately, telehealth solutions can only enhance access to care for rural populations if the necessary equipment and connectivity are available to serve them. With the potential removal of reimbursement for telephone visits associated with the end of the PHE declaration in 2023, such disparities may become compounded as cancer practices may be less inclined to offer telephone-based services without adequate reimbursement.[73]

In terms of patient-level factors, demographics such as age are relevant. Many older adults are technologically savvy, although virtual care utilization among older adults has historically been lower than in younger patients.[85,86] As the delivery of cancer care becomes increasingly technology-enabled, strategies aimed at improving digital health literacy and accessibility among older adults—such as the deployment of digital navigators and digital education resources[87]—should be considered to ensure equitable access to these services. Additionally, as discussed above, offering multiple modes of engagement (eg, computer, telephone) facilitates participation by older adults.[23,24] Encouragingly, higher adherence with PRO-based remote symptom monitoring has recently been shown to be a direct result of increased telemedicine utilization during the pandemic, with the greatest gains being observed in older adults with cancer.[88]

Beyond a patient's age, race and ethnicity warrant specific consideration. Lower digital health utilization has been reported among racial and ethnic minority populations in multiple studies.[89-91] Utilization of digital health technology by seniors, for example, is known to be significantly lower in Black and Hispanic/Latinx seniors than in White seniors, even when adjusting for educational attainment.[85] The reasons for these disparities are complex and multifaceted. Health literacy, health care mistrust, digital access, structural barriers, and language gaps have all been demonstrated to be contributing factors that can affect these and other populations.[89,91] There have been clear examples of exacerbating disparities in digital care during the COVID-19 pandemic as well. In a study conducted during the peak pandemic period in New York City, Black and Hispanic/Latinx patients, regardless of age, were significantly more likely to bypass virtual care options and seek in-person care than their peers despite the clear hazards and limitations of seeking in-person care under such circumstances.[89] A more recent analysis of telehealth utilization conducted by the United States' Office of Health Policy found that Latinx, Black, and multiracial respondents had higher odds of using telehealth services overall in 2021,[92] suggesting a promising trend. Direct community engagement and participatory approaches to assess specific digital barriers are essential to ensure equitable implementation.[93]

Health care systems and providers also face barriers to effective implementation of digital tools across an increasingly complex digital health landscape. As clinical enterprises increase their investments in digital tools, patient communication and collaboration has transitioned from phone calls and voicemails to omnichannel communication, whereby patients can use a single interface with multimodal communication options to enable synchronous and/or asynchronous connection with their clinical team. Additionally, the background architecture can be designed to manage appointment scheduling or billing with additional administrative capabilities, and clinical questions in the form of portal messages or phone calls can be delivered to clinical staff directly or triaged for added efficiency via embedded artificial intelligence–based tools such as voice recognition or bot technology. Given the increasing complexity of digital health integration, it is crucial for health systems to remain focused on a goal of enabling patients to effectively navigate the health care landscape analogous to how we use our smartphone to navigate the world. However, such care transformations can produce substantial disruptions to the clinical workflow, creating critical implementation barriers.

TENETS AND SOLUTIONS FOR BROADER USE OF DIGITAL HEALTH APPROACHES IN ONCOLOGY

Most digital tools have the potential to bridge gaps in health care inequity because they are typically more flexible, more convenient, and less dependent on patient-related resources. For example, patients can communicate asynchronously with their clinical team from their home or

TABLE 2. Tenets for Successful ePRO Implementation

Partner with ePRO vendors offering software designed for seamless EHR integration
Develop simple patient interface that is available on a wide variety of platforms
Prioritize functional ease, promote efficient workflow, and minimize alert fatigue for clinic interface
Consider frequency and duration for patient interfaces with the system
Institute time tracking of clinical alerts and alert resolution to measure system effect
Base survey instrument selection on clinical setting and application
Ensure free-text response option remains available to patients
Consider specific populations and timing for initiation, ie, at onset of new therapy
Conduct staffing capacity and needs assessment prior to implementation
Ensure process for systematic onboarding and re-enforcement for staff and patients
Establish administrative and clinical champions to oversee implementation
Refer to PROTEUS tools as a valuable resource

Abbreviations: EHR, electronic health record; ePRO, electronic patient-reported outcomes.

workplace through their patient portal, engage with ePROs, enroll and participate in clinical trials through electronic consent, conduct appointments through telemedicine, and even receive higher levels of care through continuous real-time technological solutions such as RPM and hospital-at-home programs (Fig 1). This patient-centered approach offers a degree of flexibility across the continuum of cancer care that is not possible without digital tools. Patients can continue with their daily routine, transportation is not a barrier, and they do not have to arrange care for dependents to access health care services. Additionally, digital tools provide just in time solutions with rapid turnaround. Clinics and health systems can also benefit from the use of digital tools, including the use of virtual-based teams to address staffing shortages and other challenges. However, the required infrastructure and staffing to support implementing these tools may not be feasible for some groups.

When planning to implement ePROs, it is important to consider several tenets to optimize the function of the delivery platform (Table 2).[16] First, PRO software design should integrate patient responses, notifications, and clinic actions in the EHR. Many established vendors offer this functionality. Second, the patient interface should be simple to use and available on a wide variety of platforms. Third, attention should be given to the clinic interface to ensure functional ease, prioritize efficient workflow, and minimize alert fatigue for clinical personnel. Before implementation, it is also important to choose the frequency with which a patient interfaces with the system—at routine intervals, on demand, or both—as well as duration of tool use to ensure sustainable use without generating fatigue, which decreases usefulness. Time tracking of clinical alerts and alert resolution is a useful feature that will help measure the effect of the system. Additionally, attention to survey instrument choice should be given before implementation; although many cancer-specific ePROs are already broadly implemented across systems, there may be some instances where a narrower instrument may be more useful. Patients should have the ability to document in free text in addition to reporting using close-ended, prespecified response options. Consideration should be given to which patient populations may benefit from ePRO use and when to initiate implementation—frequently with the onset of new therapy. Staffing capacity and needs assessment should be conducted before implementation to consider how patient symptom information will be managed. Finally, patients and clinic staff need systematic onboarding and re-enforcement to ensure successful implementation and championship, with administrative and clinical leaders being key to success. As clinical entities seek to incorporate ePROs in clinical practice, the PROTEUS tools can serve as a valuable resource. Practices can also partner with established vendors who have considered integration and optimal use.

The availability of tools in multiple languages would assist individuals who primarily speak a language not spoken in clinic. Use of digital health navigators, foreign language options of educational materials, and translation services could improve function for non-native English speakers. System-wide issues also require attention. Advocacy for improved broadband access in rural areas will make digital health care and other resources more available to rural areas. Internationally, implementation of mobile health technology faces unique challenges in low- and middle-income countries where access, at least initially, may be limited to middle- and high-income individuals. Investments in infrastructure and technology can democratize the availability of digital health resources for people living in these areas.[94]

CONCLUSION

The theme of this year's ASCO meeting highlights the importance of partnering with patients. Connecting with patients using ePROs and other digital health tools offers opportunities to improve care for all. They also offer the opportunity to improve health equity. However, infrastructure, patient, provider, and system-level barriers need to be addressed. Partnerships across all those levels can inform development and implementation of digital tools to meet the needs of diverse groups, both within the United Sates, as addressed here, and globally. When implemented effectively, digital tools can narrow, rather than widen, health disparities.

overview

A cancer diagnosis thrusts patients and caregivers into a foreign world of health care with systems, protocols, and norms that can leave little room for individual needs and circumstances. Quality and efficacious oncology care requires clinicians to partner with patients and caregivers to understand and incorporate their needs, values, and priorities into information sharing, decision making, and care provision. This partnership is necessary for effective patient- and family-centered care and access to individualized and equitable information, treatment, and research participation. Partnering with patients and families also requires oncology clinicians to see that our personal values, preconceived ideas, and established systems exclude certain populations and potentially lead to poorer care for all patients. Furthermore, inequitable access to participation in research and clinical trials can contribute to an unequal burden of cancer morbidity and mortality. Leveraging the expertise of the authorship team with transgender, Hispanic, and pediatric populations, this chapter provides insights and suggestions for oncology care that are applicable across patient populations to mitigate stigma and discrimination and improve the quality of care for all patients.

"No Man Is an Island"

John Donne

> No man is an island entire of itself; every man is a piece of the continent, a part of the main; if a clod be washed away by the sea, Europe is the less, as well as if a promontory were, as well as any manner of thy friends or of thine own were; any man's death diminishes me, because I am involved in mankind.
> And therefore never send to know for whom the bell tolls; it tolls for thee.[1]

INTRODUCTION

Human connection and partnerships are vital in life and in death. Patients are people who love and are loved, with lives outside of their illnesses and who often identify with or belong to a family or community outside of the health care system. These are people with a past, a present, and a future, albeit a sometimes uncertain and fraught future.

Yet in health care, when people become patients, too often they are expected to function as an island entire of itself. This is despite health care in the United States (and plausibly in other Western health care systems) having grown increasingly complex, fragmented, and difficult to navigate.[2] Patients are, therefore, heavily reliant on their physicians at their most vulnerable times. The patient-physician relationship is the backbone of patient care and translates to positive outcomes, including for patients with cancer. In a study of 283 patients with breast or lung cancer, health-related quality of life was associated with the doctor's level of respect, patient involvement in decision making, and patient satisfaction with the quality of their care.[3] Conversely, in another study, poorer experiences of the patient-physician relationship were related to greater fears of cancer recurrence.[4] For women with breast cancer, psychosocial interventions improved quality-of-life measures and 12-month cancer survival.[5]

Patient-centered care includes (1) patient involvement in decisions and respect for patients' values, (2) clear information and communication, (3) access to reliable care, (4) emotional support and empathy, (5) involvement and support for family and caregivers, (6) continuity of care and smooth transition between health care settings, (7) physical comfort, and (8) effective treatment by trusted professionals.[6] Patient-centered care allows oncology clinicians and oncology systems to adjust to or account for the contradictions and limitations of our algorithms to create better care for all patients. Davis et al[7] suggested that quality of patient-centered care might be defined by the achievement of providing the care that the patient

Author affiliations and support information (if applicable) appear at the end of this article.

PRACTICAL APPLICATIONS

- The patient-physician relationship is the backbone of patient care and affects outcomes for patients with cancer.
- Health care systems' protocols, regulations, and norms often do not fit neatly with patients' and caregivers' unique needs or lives.
- Oncology clinicians must recognize that personal values, preconceived ideas, and established systems may exclude certain populations and potentially lead to poorer care for patients.
- Partnering with patients and caregivers allows clinicians to understand and incorporate patient and caregiver needs, values, and priorities into information sharing, decision making, and care provision.
- Learnings from transgender, Hispanic, and pediatric patients can be applied at a direct patient and systems level across oncology care more broadly to enhance equitable and efficacious care for all oncology patients and caregivers.

needs in the manner that the patient desires at the time that the patient desires.

This chapter will focus on three patient populations, transgender, Hispanic, and pediatric populations, with whom the authors have experience and will be the focus of invited presentations at the ASCO 2023 Annual Meeting. We highlight the importance of partnering with patients and caregivers to promote inclusive and equitable oncology care, provide oncology clinicians with skills to care for these populations, and apply lessons learned to provide more efficacious care for all patients.

PART 1: MITIGATING BARRIERS TO ONCOLOGY CARE EXPERIENCED BY TRANSGENDER PEOPLE

Ontological Contradictions Leading to Stigma

Medical concepts, or ontologies, of the body include the notion that sex is an immutable fact of the body and that this encompasses both biological constructs—including karyotype, hormonal milieu, anatomy, and body size—as well as gender, that is, one's sense of themselves as a man, woman, nonbinary, genderqueer, butch, femme, or something else.[8] The motivations for these ontologies are inseparable from gender-based oppression and served to distinguish so-called men and women to establish social hierarchy between them.[9] The repercussions of these ontologies are various and include the impacts on transgender and intersex people.

Ontological oppression[10] is structural harm that occurs when one's body or experience does not fit into pre-established categorical understandings. For example, medical ontologies include the notion that someone whose sex is female will have the chromosomes XX, a vagina, uterus, fallopian tubes, ovaries, and an estrogen- and progesterone-predominant hormonal milieu and be a woman. Thus, transgender or intersex people whose bodies, experiences, and/or genders do not fit these pre-established ontologies experience stigma, discrimination, exclusion, and poor care.[11-13]

Ontological oppression is also salient in oncology care, in which transgender people experience stigma, paternalism, discrimination, denial of care, and lack of safety.[14-16] Qualitative research has suggested that one reason clinicians stigmatize transgender people is to manage their lack of knowledge or familiarity with transgender bodies and experiences.[17] When transgender people's bodies do not fit within medical ontologies, clinicians can feel confused or uncertain, in contrast to transgender people who often know more about their bodies and health needs than their physicians.[13] This upsets the usual balance of power on the basis of clinical expertise. Clinicians may use stigma and discrimination to reset the balance of power.[17]

Instead, partnering with transgender people allows for the possibility that transgender people are not just an exception to an algorithm but an opportunity to rethink its validity and utility.[18] Instead of stigmatizing transgender people, oncology systems could re-envision sex, hormonal milieu, karyotype, anatomy, and size as distinct categories, which are separate from gender. Such new ways of seeing bodies and disease would end exclusions of transgender and intersex people. Shifting these categorical assumptions could also be a first step toward building algorithms and categories that are more precise. If sex were no longer used as a proxy for other biological constructs—for example, if data regarding anatomy, hormonal milieu, body size, and karyotype were collected on trials instead—the role of each of these in cancer pathology could be assessed independently and understood more deeply, setting the stage for more efficacious care for all people with cancer.

In the section that follows, we describe manifestations of conflated concepts of gender, sex, and biological factors in disease discourse, laboratory values, and chemotherapy dosing that set the stage for structural oppression and poor care. We also make suggestions to shift these ontologies to decrease the impetus for oppression of transgender people, intersex people, and additional people who may not conform to expectations on the basis of these conflated concepts. Shifting these categorical assumptions about bodies and disease could also be a first step toward more precise data and care for all people with cancer.

Disease Discourse, Misgendering, and Stigma

In oncology, one extension of the ideology that gender is an immutable fact of the body is that certain cancers are attributed only to people of specific genders. For example, prostate cancer is associated with men. This is manifested in care settings that are gendered with language, symbols, and iconography to reinforce these concepts. For example, cancer centers in which people are treated for ovarian, endometrial, fallopian tube, cervical, and other cancers may be named Center for Women's Cancers. The walls of such centers may be pink, and the walls may include photographs of women. In contrast, educational materials for people with prostate cancer may be blue and may contain images of ties or mustaches. Such spaces may implicitly exclude intersex people, men, or nonbinary people. Such settings may also create circumstances in which clinicians and staff may be more likely to use pronouns, an honorific, or gender marker that imply the wrong gender for patients, a phenomenon referred to as *misgendering*.[19] Similarly, curricula, educational materials, and guidelines for clinicians may also associate certain cancers (eg, testicular) with specific genders (eg, men), creating circumstances in which clinicians will be unprepared to see intersex or transgender patients and may respond by misgendering or stigmatizing them. Clinical trial documents and eligibility criteria may also contain these concepts, which can exclude transgender people from clinical trials and signal to transgender people that trials were not developed with them in mind.[20]

Laboratory Values and Drug Dosing

Laboratory value reference ranges have been derived on the basis of cohort or population studies of large groups of people who are categorized as women or men. Such laboratory values also reflect the idea that sex is indistinguishable from a variety of biological factors, including organ size, muscle mass, menses, hormone levels, and bone health, that influence laboratory values such as hemoglobin, iron studies, calcium, liver function tests, and creatinine clearance. Transgender and intersex people have bodies that do not match such categorical assumptions and thus often have laboratory values that are persistently flagged as abnormal when they may not be.[21,22] Other people may also be harmed by laboratory value reference ranges that have been determined on the basis of mean values and confidence intervals for so-called men and women. For example, many nontransgender women may have their iron deficiency anemia go undiscovered because of gendered laboratory reference ranges that have lower values for hemoglobin, hematocrit, ferritin, and transferrin saturation than for men. An extension of this concern is that dosing for some chemotherapeutics are calculated by creatinine clearance, which is based on a sex/gender marker. To our knowledge, no data exist about how these ranges apply to transgender and intersex people, but some data suggest that these algorithms may lead to drug toxicity in people with certain body composition.[23]

Partnering With Patients and Caregivers

Qualitative data suggest that gendered assumptions exclude transgender people from oncology care and that these exclusions are reinforced using misgendering, stigma, and paternalism. Individual oncology clinicians can take immediate steps to ensure that their care is accessible and efficacious. First, oncology clinicians can ask for and use the terms that patients tell us to use about them and their bodies, including their name, pronouns, honorific, and words to describe their anatomy and consistently use these with colleagues and in the electronic health record. One participant in a qualitative study suggested, "Use the pronouns that the patient told you to use. It's not enough to use it when you're talking to the patient and they're in the room, you need to use it in your notes. You need to use it when you're talking to other providers about the patient. You need to use it all the time. The same goes for the gender identity…It's very frustrating to see notes [with phrases] like, 'She wants to be called he.'"[24]

Second, oncology clinicians can creatively prioritize patients' desired interventions for their oncology care. Guidelines and educational norms suggest that we prioritize anatomy-sparing interventions in the setting of cancer (eg, lumpectomy over mastectomy). When several treatment options offer equivalent outcomes, however, the principles of shared decision making stipulate that patients have agency over their decisions. In some cases, patients may prefer more surgery rather than less for a myriad of reasons, including the relationships individual patients have to these parts of their bodies.[14,25] For example, a patient may desire orchiectomy rather than androgen deprivation in the setting of prostate cancer.[14]

Third, we must emphasize patient priorities when making decisions about gender-related hormone therapy or surgeries in the setting of cancer treatment in the absence of clear data. Hormone therapies and surgeries decrease suicidality and improve quality of life for transgender people.[26] Symptoms and illness are often misattributed to these interventions likely because they are a surrogate target for transphobia.[27] Little is known about the outcomes of transgender people with hormonally driven cancers who take hormone therapy (eg, testosterone in the setting of androgen receptor–positive breast cancer). Oncology clinicians thus navigate difficult waters with little concrete guiding data. More research is needed to support such conversations. In the interim, if patients or clinicians have questions about the safety of hormone therapy in the context of cancer treatment, we suggest clinicians (1) specifically

ask about patients' priorities in regard to hormone therapy, (2) investigate whether any evidence exists to suggest hormone therapy may worsen oncology outcomes, and if so, present these data to the patient, and (3) follow the patient's lead in regard to decision making, balancing the knowledge that hormone therapies are lifesaving interventions for transgender people who desire them, the largely unknown risks of hormone therapy in the setting of cancer treatment, and ethical considerations including respect for persons, beneficence, and justice.

On a broader structural level, oncology clinicians, administrators, and educators must update potentially oppressive habits by distinguishing sex from other biological constructs as well as from gender and accordingly revising oncology discourse in guidelines, curriculum, clinical documentation, and elsewhere as has been done by ASCO, which recently changed their guideline template to emphasize the importance of gender-neutral guidelines.[28] Laboratory values and chemotherapy dosing must also be reimagined and recalculated not on the basis of a sex/gender marker but more precise data such as hormone levels, body surface area, or body composition as is being done in the setting of race-based calculations of creatinine clearance.[29] In summary, transgender and intersex people with cancer face ontological oppression because their bodies, experiences, and preferences may not fit prevailing assumptions. Clinicians can mitigate the oppression transgender people face by following patients' leads in terms of describing and caring for their bodies and by making structural changes that can improve care for all patients.

PART 2: SHIFTING THE POWER DIFFERENTIAL IN THE PATIENT-PROVIDER RELATIONSHIP BY EMPOWERING HISPANIC PATIENTS AND THEIR CAREGIVERS

Eliminating long-standing disparities and inequities in the delivery of oncology care, including research and clinical trial participation, requires a transformative vision that involves health system leaders, diverse research teams, patients and their families, and affected communities. As proposed by Harold Freeman over a decade ago,[30] there is a disconnect between the research discoveries that largely occur in academic institutions and the delivery of these to underserved communities, which represents a key determinant of the unequal burden of cancer morbidity and mortality in the United States (Fig 1). With the rapid emergence of precision oncology and immunotherapy, we urgently need solutions to overcome the limited access of underrepresented racial and ethnic groups to cancer therapies so that every person with cancer benefits.[31] In the case of Hispanic patients, community-engaged and culturally and linguistically appropriate strategies targeting patient-, provider-, and institutional-level factors are essential to address the disconnect between what we discover and what we deliver. Health systems must play a role in bridging this gap by meeting the needs of individual patients and their caregivers to mitigate language, cultural, and other barriers to quality oncology care.

Barriers to Clinical Research Participation in Adult Patients

The University of California Moores Cancer Center (MCC) is located in San Diego County, one of two US-Mexico border counties in California. MCC's Community Outreach and Engagement (COE) team works diligently to engage patients, families, providers, and the MCC catchment area community, 35% of whom are Hispanic, to assess and address barriers related to oncology care delivery, including research participation and clinical trial enrollment. This work is guided by a formal framework (Fig 2) that was adopted from previous work[32] and largely focuses on Hispanic patients and their families.

Patient-Provider Language Concordance

Delivering linguistically competent care is critical to serving patients who have limited English proficiency (LEP) and represents a key strategy to help reduce health disparities and inequities. Current acceptable standards of communication with patients who have LEP include providers communicating through professional interpretive services or bilingual providers communicating in the patients' preferred language. Our research examined the effect of patient-provider language concordance on patient satisfaction in adult Spanish-speaking patients with cancer.[33] We found that, compared with patients who receive care leveraging interpreter services, patients cared for by a Spanish-speaking oncologist reported significantly improved general satisfaction (P = .001). Spanish-speaking patients served by a Spanish-speaking oncologist also reported improved satisfaction with quality of care (P = .005), care team interpersonal skills (P = .004), communication (P = .018), and time spent with patients (P = .028). Patients also rated direct Spanish language care higher in perceived opportunity to disclose concerns (P = .001), physician empathy ($P < .001$), confidence in physician abilities (P = .001), and general satisfaction with their physician ($P < .001$). Analyzing the content of consultation encounters revealed further differences between the two

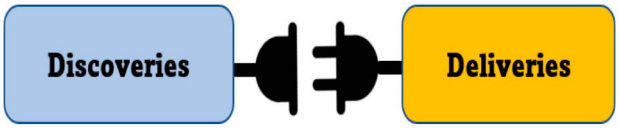

FIG 1. The disconnect between lifesaving discoveries and their delivery to underserved communities.

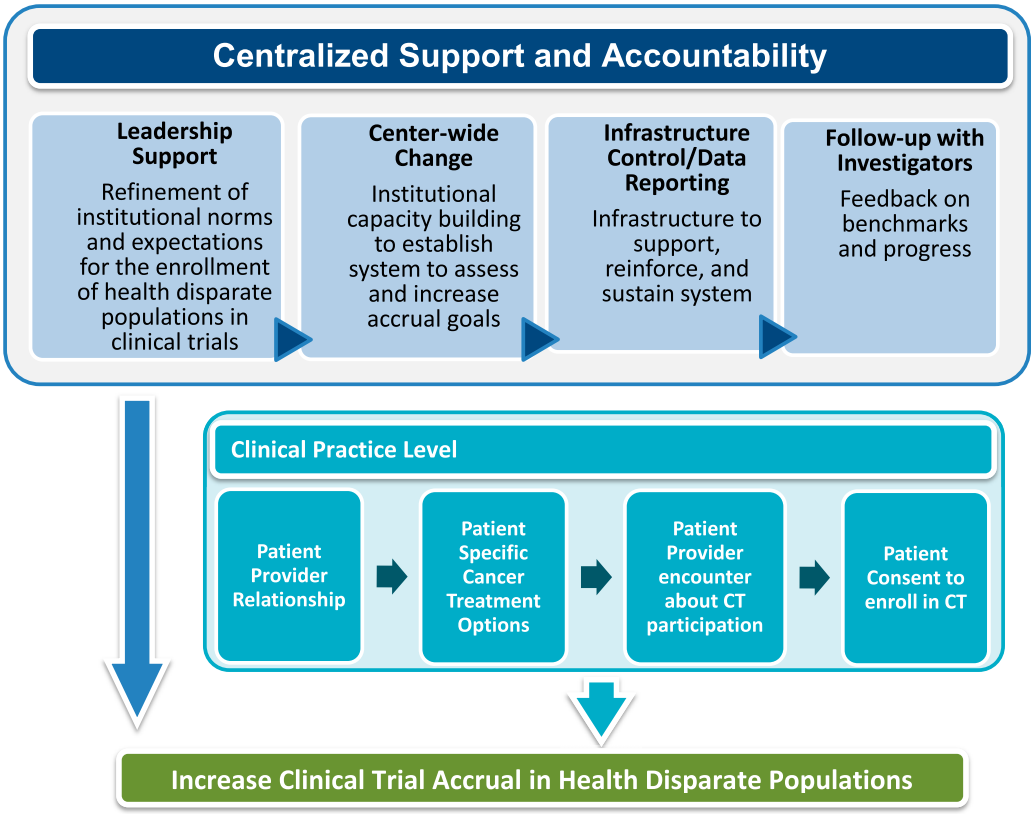

FIG 2. Moores Cancer Center approach and framework for clinical trial accrual. There is a need to centralize recruitment of health disparate populations to clinical trials, have organizational accountability, and have continued monitoring. Structural changes are needed on four levels: (1) leadership support, (2) center-wide policy change, (3) infrastructural process and control, and (4) follow-up with clinical investigators. CT, XXX.

groups, with the direct Spanish language arm having more physician dialog related to patient history verification ($P = .01$) and partnering activities ($P < .0001$). Additionally, patients in the direct Spanish language arm were more likely to initiate unprompted speech ($P < .001$) and asked their providers more questions ($P = .007$). These results underscore the importance patient-provider language concordance plays in providing quality care to Hispanic patients with cancer.

Provider and Patient Surveys and Interviews

Using the established framework presented in Figure 2, the MCC Clinical Trials Office (CTO) and COE teams conducted qualitative and quantitative assessments among patients, caregivers, and oncology providers (physicians, patient navigators, and social workers) to assess barriers and facilitators to recruiting and enrolling patients from underrepresented groups into clinical research and clinical trials.

Provider feedback. The most common barriers noted by providers were patient-clinical team language and cultural barriers (92%), logistics/transportation barriers (89%), patients' lack of knowledge about clinical trials (69%), negative attitudes and beliefs about clinical trials (61%), and lack of payment/insurance coverage for clinical trials (58%). One recurring theme was limited availability of translated consents to overcome language barriers. Interviewed providers who reported success in recruiting Hispanic patients underscored the importance of understanding patient needs, fears, and challenges. For example, one common challenge relates to geographic constraints. Although public transportation options near clinical trials sites is viewed as a solution, in actuality, transit time and transfers prohibit true access by patients with cancer who reside far away from the clinical site.

Patient feedback. We conducted qualitative interviews to understand factors that influence and impede participation in cancer research and clinical trials among English- and Spanish-speaking Hispanic patients with breast cancer and their caregivers (Table 1). The findings show that Hispanic patients with breast cancer have a high interest in participating in clinical trials, particularly when clinical teams practiced respect, built trust, and considered study participant needs. There were clear gaps between patient and provider understanding, exacerbated by language and

cultural barriers accentuating the power differential in the patient-provider relationship and limiting the ability of patients to self-advocate and identify areas of misunderstanding. A strong theme that emerged from the interviews with patients was a general unfamiliarity with research that was compounded by patients feeling overwhelmed with and confused about diagnosis and treatment information. Patients also often described an inability to establish trust and comfort with the many providers they encountered, particularly when there was language discordance or fears about immigration status for themselves or loved ones. These unsettled feelings prevented patients from engaging in dialog around added complexity, such as considering a clinical trial or research study, even it was offered to them. The importance of care team members dedicating time to establish trust and clear communication (with professional interpreters for patients with LEP and clinicians without Spanish proficiency) was a crucial theme woven throughout patient interviews.

After these assessments, systematic solutions were implemented at the MCC to address some of the barriers, which centered on culturally and linguistically concordant care and clinical trial navigation. These include (1) monthly COE/CTO reporting and monitoring of racial/ethnic trial accrual; (2) Spanish language (and other languages) consents available alongside English language consents in multiple short-form formats to streamline consenting for patients who require urgent access to studies; (3) annual/biennial cultural competency trainings for CTO staff; (4) hiring racially and ethnically diverse (approximately 75% non-White) and bilingual (approximately 33%) clinical trial coordinators and staff; and (5) hiring bilingual navigators representing eight languages other than English, centered on culturally and linguistically concordant care and patient navigation to address barriers. On the basis of these findings, recommendations are offered to increase the accrual of Hispanic patients to clinical research and trials (Fig 3).

Caregiver-Provider Communication in Hispanic Families of Children With Cancer

Although childhood cancer survival has significantly improved to more than 80%, driven in large part by participation in multicenter clinical trials, racial/ethnic disparities persist. Compared with non-Hispanic White children, Hispanic patients have significantly higher mortality, relapse rates, and poorer survival.[34-36]

The MCC team's research related to equity in pediatric oncology care delivery has largely focused on patient/caregiver-provider communication during informed consent for clinical trials by assessing social determinants of health, with a particular focus on health literacy (HL) and LEP. Delivering informed consent in the pediatric oncology setting poses significant challenges because of the urgency to begin treatment, the lengthy informed consent, and lack of formal informed consent training for providers,[37] which influence patient-provider communication during informed consent.[38,39] Our published work[37] on the role of HL and acculturation on informed consent outcomes showed that limited HL was significantly associated with lower perception of voluntariness ($P = .001$). Moreover, limited HL was significantly associated with Hispanic ethnicity ($P < .001$) and Spanish language spoken at home ($P < .001$). In addition, limited HL and Spanish language were significantly associated with lower informed comprehension ($P < .001$).[40] These findings suggest that caregivers with limited HL or LEP may not fully comprehend the informed consent for cancer clinical trials and thereby not truly make informed decisions. To improve patient-provider communication during informed consent, it is imperative that discussions be tailored to the language, HL, and cultural needs of parent/caregiver. Using in-person interpreters facilitates comprehension of informed consent content in different languages.[41,42] For caregivers who hesitate to ask questions, engaging them in decision making and checking their comprehension using techniques such as the teach back method can improve patient-provider

TABLE 1. Perceptions of Barriers and Facilitators to Clinical Research and Trial Participation Among Hispanic Patients With Cancer

Barriers	Facilitators
Patient-provider language and cultural discordance	Study information is delivered in-person
Lack of information about cancer clinical trials or research	Study location is geographically close to their home
Clinical trial not being offered	Provide appointment reminders by phone or text
Fear of potential risks in participation	Keep appointment duration short
Competing focus and confusion between patient's cancer treatment and clinical trial/research project activity	Study uses less invasive procedures and treatments
Patients' lack of time	Study personnel deliver a supportive experience (ie, respectful and professional) during enrollment and throughout the study
Inability to establish trust and comfort with care team providers	

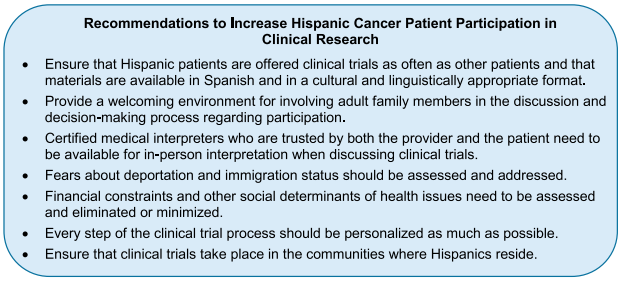

FIG 3. Recommendations to increase the participation of Hispanic patients with cancer in clinical research.

communication.[39] This method requires that patients/caregivers are asked to recount what they have been told in the informed consent discussion.[43] Moreover, staged informed consent delivery,[44] decision aids, patient navigation, and interventions at the provider and health care system levels[31,37] could potentially improve patient-provider communication during informed consent.[45,46]

In summary, addressing the disconnect between lifesaving research discoveries and delivery of these to underserved communities represents an unprecedented opportunity for achieving equity in oncology care delivery so that all patients have an opportunity to benefit from lifesaving cancer interventions. Instead of patients and their caregivers assuming the responsibility to adapt to the health system's environment when receiving care, health care organizations serving Hispanic patients with cancer need to proactively meet the unique needs of these patients. Effective patient-provider communication is one essential component of high-quality oncology care delivery. For Hispanic patients and their providers, communication should be tailored to the individual's language, culture, background, and HL and education levels.

PART 3: BALANCING THE NEEDS OF CHILDREN AND CAREGIVERS IN PEDIATRIC ONCOLOGY CARE

In pediatrics, it is vital to partner with both patient and caregiver as the unit of care is frequently, if not always, the family unit and not the patient in isolation.[47] Children exist within their family context, and family members' influence is central, pervasive, and enduring.[48] Parents and family members are fundamental in pediatric care[48] and serve as a conduit between children and health professionals during assessment and treatment interactions. The child's experience and wishes, articulated independently of the family unit, are equally important. Incorporating the voice of both child and caregiver and balancing the needs of both parties are vital. Although some of the detail outlined below relates to incurable cancer and life-limiting pediatric illness, the learnings are relevant to pediatric oncology care (and arguably across the age spectrum), regardless of treatment intent.

Balance of power in a therapeutic relationship is an important consideration. Children can be at risk of not being heard or listened to, and so too can parents or caregivers. This may be due to tensions about whose needs to prioritize, particularly when there appear to be competing interests between the child and the caregiver. Health professionals may appear to bear the ultimate power in the relationship, and with this comes a responsibility to hear and balance the needs of both child and caregiver. For example, children may wish to be involved in diagnostic and prognostic conversations while their parents may prefer to exclude them from such conversations.

Oncology clinicians and oncology systems may make assumptions regarding children's presumed lack of understanding about their illness, with implications about the degree to which they are involved in their own health care. Children understand more about illness than what has previously been thought.[49] Age is not the only factor that determines a child's understanding and engagement with illness. In her ground-breaking book, *The Private Worlds of Dying Children*, Bluebond-Langner illustrated the impact of experience, culture, and society on children's understanding of health and illness.[50] Even when not included in discussions about their leukemia diagnosis and prognosis, children on the oncology ward came to understand what was happening to them and to the children around them. It became clear to Bluebond-Langner that terminally ill children were aware that they were dying, before death was imminent, yet they tended to keep this knowledge secret from their parents and caregivers.

The 2009 European Standards of Care for Children with Cancer articulate that hospitalized children and young adults should have access to appropriate information.[51] However, the guidelines also recognize the role of parents as partners in the care of their sick child and their crucial role in supporting their sick child through illness. Therefore, although developmental age and stage are important when approaching conversations with a young person about their cancer diagnosis and treatment options, this must be done within their family construct and dynamics.

Family and Loved Ones—The Caregiver Role

Roles are tied into an individual's identity and sense of self.[52] A parent's role is to sustain, care, advocate for, and protect their child. This role is challenged when a parent's sense of control is stolen away by their child's cancer diagnosis, leaving them at the mercy of strangers (health professionals) and institutions (hospitals). Parents of children with cancer typically think about the features that make them a good parent to their sick child, but these attributes vary between parents and may change over time.[53-55] Priorities may include making informed medical care decisions, making

sure the child feels loved, and advocating for the child.[53] Of course, these attributes are not mutually exclusive.

In the pediatric cancer world, partnering with caregivers can involve exploring what helps parents to feel like they are meeting their role as caregiver to their child. Understanding drivers for parents' behaviors can promote a therapeutic relationship between parents and clinicians. For example, when parents face the devastating news that their child's cancer has progressed despite treatment, they may be confronted with seemingly impossible decisions such as the pursuit of experimental treatments versus a symptom-based palliative approach to care. Naming and normalizing these difficult dilemma that parents face can open a space for parents to share their hopes, fears, and priorities.[56] This in turn can help guide discussions about prognosis and treatment decisions. Regret and unfinished business may be associated with distress for parents of children with cancer, both while caring for their child and in bereavement.[57] Health professionals can play a role in mitigating regret and unfinished business by supporting their decision making and validating their choices.[57]

A cancer diagnosis throws a child and family's world into turmoil; roles, priorities, and day-to-day life need to be adjusted to accommodate the child's new care needs.[52] Understanding the structure and dynamics of a family is key for health professionals to provide tailored delivery of health information and emotional and decision-making support. An important dynamic for health professionals to uncover relates to the communication style and information needs of a family.

Glaser and Strauss described awareness contexts to illustrate what patients might know about their illness trajectory; for example, in an environment of closed awareness, families and care providers protect patients from the secret of the seriousness of their illness, whereas in an open awareness context, all parties share honest and open communication.[58] Mutual pretense refers to the collusion between patients, families, and even care providers to avoid or deny the seriousness of an illness and the possibility (or certainty) of death.[58] Both parties are aware of what is happening, but neither acknowledges this openly. Mutual pretense may be used to allow the maintenance of a narrative that the right treatment will restore health and a normal life, and health providers may perpetuate this narrative because of a fear of causing additional harm by taking away hope.[59] Bluebond-Langner expanded on the phenomenon of mutual pretense in the pediatric context, illustrating how parents and children may avoid talking about illness and death to protect each other. In the pediatric context, mutual pretense protects and maintains the social norm and expectation that children in Western society have a future.[50,52] It is important to remember that children equally engage in mutual pretense and seek to protect their parents from pain and suffering. This may occur, for example, by minimizing symptoms, physical or emotional, and avoiding talking about their cancer or their worries.

Child Role—The Patient Role

In pediatric oncology care, the child should be at the center of care and decisions, and their voice should be sought, listened to, and respected. However, as mentioned earlier, it must be recognized that the child exists within the tapestry of their family. Balancing the needs of children and caregivers can be challenging.

Studies now illustrate that children as young as 7 years can complete patient-reported outcomes and provide a voice in their symptom assessment. An important symptom assessment tool is the multidimensional Memorial Symptom Assessment Scale (MSAS) that inquires not just about the presence of a symptom but also its impact. If a symptom has occurred, the MSAS tool asks about its frequency, severity, and related distress, providing rich information to health professionals about where to focus time and management. Children with advanced cancer report high physical and psychological distress, for example, from pain, fatigue, drowsiness, and irritability.[60-62]

From a prognostic and information perspective, young people with cancer often want honest information, in the form of human contact as opposed to the internet. They generally want truthful information, even if the information is confronting, but conveyed in a way that leaves room for hope.[63] Importantly though, no one size fits all; some young people do not want information while for others, withholding information can exacerbate loneliness and fear.[64]

Shuttle Diplomacy—A Model for Bridging Gaps in Communication

Power (im)balances should not preclude access to the right amount and type of information for children and their caregivers. Parents may ask health professionals to hide information about their child's diagnosis or prognosis for fear of causing them distress and harm. As discussed earlier, this may be despite the child's awareness of their condition and desire for information while simultaneously perhaps wanting to protect their parents.

To truly partner with children and their caregivers and meet them where they are, health professionals are tasked with gently challenging rather than perpetuating a narrative of mutual pretense. This requires a sensitive approach to bridge gaps in communication and an awareness of the broader family context and culture of communication: How does this child-parent dyad usually communicate difficult matters? What are their preferences for receiving information, and who would the child like to deliver and interpret their health information? What are the parents' views and preferences in guiding their child through

TABLE 2. Summary of Clinical Practice Level Recommendations

Mitigating barriers to oncology care experienced by transgender people
Enquire about and use the terms that patients tell clinicians to use about them and their bodies, both in consultations and in health record documentation
Ask and partner with patients about their preferences and priorities and avoid assumptions, especially regarding cancer gender-related hormonal therapy and surgery
Provide patients with as much information as possible and work with them to weigh the risks and benefits in the absence of data
Considering cultural differences to improve quality cancer care
Include language and cultural concordant staff on study teams (eg, bilingual/bicultural investigators and study personnel)
Provide a welcoming environment for involving family members in discussions related to care delivery and research study recruitment
Encourage cultural competency training opportunities for study team that are specific to communities of focus
Establish partnerships with community providers and health organizations to assist with education, recruitment, retention, and dissemination
Form sustained partnerships between clinical trials office and community outreach and engagement teams
Balancing the needs of children and caregivers in pediatric cancer care
Consider information provision in the context of a child's developmental and chronological age, as well as their family dynamics and communication style
Utilize validated patient-reported symptom scales and outcome measures for children with cancer
Be sensitive to awareness contexts, for example, closed awareness or mutual pretense where the child and their caregivers may be aware of, but choose not to speak of, the seriousness of the child's illness
Where possible, engage in shuttle diplomacy to bridge gaps between the child and caregivers' experiences and worries

difficult conversation? Shuttle diplomacy, or diplomatic negotiation, is a process whereby health professionals aim to help parents feel heard and respected and at the same, help them to see their child's experience. For example, taking the time to understand why a parent does not want their child to know something allows an opportunity for exploration and discussion about parental fears and worries. In addition, sharing with parents that their child may already be aware and worried may open a space for parents to consider having difficult conversations with them. The goal of shuttle diplomacy is for parents and children to have their voices heard and respected and to enhance the relationship between them, not to achieve truth telling at all costs. When considering children in decision making, Bluebond-Langner described the importance of avoiding deceit and coercion and respecting the right to information, providing this is what the child desires. However, "the challenge in creating a role for children in decision making is to balance these values with the social fabric of family life and the rights that are accorded to parents in light of their responsibilities for their children" (p 337).[65] Ultimately, an understanding that unraveling the fabric of a family may be more harmful than information provision itself is an important underpinning of illness conversations with families and children in pediatric oncology care.

SUMMARY

Oncology clinicians are in a unique and privileged position of caring for people at some of the most vulnerable times of their lives. This vulnerability is multilayered; for example, structural and individual vulnerability may relate to the patient's age, gender, or cultural context, and from the patient's point of view from the cancer diagnosis itself, the shattered world of normalcy, the uninvited contemplation of mortality, and the grueling nature of cancer treatment. Focusing on the three specific populations, transgender, Hispanic, and pediatric patients, this chapter has described three common themes: (1) the risks that prevailing assumptions may exert on preference-sensitive decision making (hormonal treatment in transgender patients; differences in language concordance, even in the presence of translators to enter clinical trials; and how children understand their disease); (2) the imposition of institutional and societal norms, including normal laboratory values; and therefore, (3) the importance and value of truly partnering with patients and caregivers in the delivery of oncology care on interpersonal and systemic levels. A summary of clinical practice recommendations from the three patient groups is shown in Table 2.

When people become patients, they are thrust into health care systems whose protocols, regulations, and norms often do not fit neatly with patients' and caregivers' unique needs or lives. Clinicians well-steeped in the culture of health care can make unbidden assumptions about their patients' circumstances, priorities, and fears, which in turn can lead to missed opportunities for appropriate

information provision, shared decision making, and equitable care. Caregivers play a vital role in supporting patients with their practical and emotional needs and may influence patients' treatment decisions. Importantly, caregivers have their own experience of their loved one's illness with individual support needs that may affect patient care. Learnings from the three patient groups described in this chapter can be applied at a direct patient and systems level across oncology care more broadly to enhance equitable and efficacious care for all oncology patients and caregivers.

Using Measurable Residual Disease to Optimize Management of AML, ALL, and Chronic Myeloid Leukemia

Simone E. Dekker, MD, PhD[1]; Delphine Rea, MD, PhD[2,3]; Jean-Michel Cayuela, PhD[2,4]; Isabell Arnhardt[5]; Jessica Leonard, MD[6]; and Michael Heuser, MD[5,7]

Overview

In this review, we discuss the use of measurable residual disease (MRD) in AML, ALL, and chronic myeloid leukemia (CML). Our aims were to review the different methodologies for MRD assessment; describe the clinical relevance and medical decision making on the basis of MRD; compare and contrast the usage of MRD across AML, ALL, and CML; and discuss what patients need to know about MRD as it relates to their disease status and treatment. Finally, we discuss ongoing challenges and future directions with the goal of optimizing MRD usage in leukemia management.

INTRODUCTION

AML, ALL, and chronic myeloid leukemia (CML) are heterogeneous diseases which exhibit widely variable prognoses that are a function of both disease and patient characteristics. Both treatment decisions and prognosis are dependent on patient disease status, which requires accurate assessment of measurable residual disease (MRD). MRD is defined as the persistence of leukemic cells after treatment at levels below morphologic detection.[1,2] MRD below certain thresholds is associated with longer progression-free survival (PFS) and overall survival (OS) in patients with leukemia, and MRD is increasingly used as a secondary end point in clinical trials.[3-6] In this article, we review the usage of MRD and its clinical implications in patients with AML, ALL, and CML.

MRD MEASUREMENT TECHNIQUES

MRD assessment may be performed via three different modalities: multiparameter flow-cytometry (MFC), quantitative polymerase chain reaction (qPCR), or next-generation sequencing (NGS). Specimens for MRD assessment can be obtained via peripheral blood or from a small volume of first pull bone marrow to avoid hemodilution. For each leukemia type, MRD is usually assessed after initial treatment, serial testing during therapy, and also during follow-up once therapy has been completed. Yet, there are significant differences between MRD assessment methodologies, and sensitivities vary across each leukemia subtype. The sensitivities, advantages, and disadvantages of each MRD assessment method across leukemia types are briefly discussed below and summarized in Table 1. Detailed reviews on these techniques are available in the literature.[1,10] MRD negativity or undetectable MRD refers to an MRD result that is below the recommended prognostic threshold. This threshold is discussed below for various diseases (see also Figs 1–3 and Table 1). MRD may be detectable below the prognostic threshold but above the assay's limit of detection. Different approaches may be used for this so-called MRD at low level, as discussed below.

The molecular and immunological heterogeneity of AML requires tailoring the MRD assessment method(s) for specific patient populations (Fig 1). Per the National Comprehensive Cancer Network (NCCN) and European LeukemiaNet (ELN), the first step in MRD assessment for AML should focus on molecular mutations such as *NPM1* and fusion oncogenes using qPCR. Although molecular qPCR-based techniques are sensitive, their disadvantage is that they can only be applied in a subset of patients harboring these genetic mutations.[7] If these mutations are absent, MFC can be used if specific immunophenotypes are present. Although NGS can assess and quantify mutations with prognostic value in patients with AML,[11-14] it is not yet recommended as a stand-alone technique in routine clinical practice because of lack of standardization and incomplete validation of its target mutations.[7] To use MRD prospectively as a predictive biomarker, it is important to standardize MRD across all laboratories. The ELN-DAVID MRD network and the Foundation of the National Institutes of Health (FNIH) Biomarkers Consortium very actively promote standardization of all MRD assays.[15] This has resulted in a program for external quality assessments (EQA), which are offered quarterly by United Kingdom National External Quality Assessment Service (UK-NEQAS) and should be followed by all laboratories.

PRACTICAL APPLICATIONS

- Measurable residual disease (MRD) is a critical diagnostic tool that predicts disease progression and is increasingly used as an important end point to monitor disease status and evaluate novel treatments for leukemia.
- In AML, MRD is evolving toward a clinical decision support tool, but standardization of the technology across laboratories and among technologies need international efforts.
- MRD has a major impact on clinical decision making in patients with ALL. For example, MRD status influences treatment regimens and the decision to proceed with allogeneic hematopoietic cell transplantation. Emerging data suggest that more sensitive modalities that use next-generation sequencing are superior in predicting outcomes in patients with ALL.
- MRD is well standardized in chronic myeloid leukemia and is fully established to guide treatment decision during treatment and before and after stopping tyrosine kinase inhibitors.
- MRD technologies rapidly evolve toward sequencing-based assays, but machine learning and new flow cytometers also innovate cell-based assays.

MRD in ALL is typically assessed via MFC (sensitivity of 10^{-4}), qPCR for patients with Philadelphia chromosome–positive ALL (Ph+ ALL; sensitivity of 10^{-4} to 10^{-5}), or NGS (sensitivity of 10^{-6}; Table 1).[8] NCCN guidelines state that MRD testing for ALL must have a sensitivity of at least 10^{-4}; however, emerging data suggest that more sensitive modalities are superior in predicting outcomes in patients with ALL.[16,17] In light of these findings, the majority of academic centers in the United States are now incorporating NGS-based platforms for MRD monitoring. One US Food and Drug Administration (FDA)–approved NGS-based test is currently available in the United States (ClonoSeq, Adaptive Biotechnologies, Seattle, WA). This test follows immunoglobulin H (IgH) rearrangements in B-ALL and T-cell receptor gene rearrangements in T-ALL, and approximately 90% of patients will have a trackable clone.[18] This assay is not clone-biased, meaning that it can detect new clones as they arise over time.[19] In addition, there is evidence to suggest that NGS-MRD monitoring in the blood has a similar sensitivity to that of the bone marrow, allowing for more frequent monitoring without the need for invasive procedures.[20] The main shortcomings of NGS include requiring a large number of cells, cost, and long turnaround time which may delay clinical decision making. By contrast, MFC is widely available, relatively inexpensive, and results are available quickly. However, there is no standardized MFC testing available in the United States, and sensitivities vary across centers.

Detection of residual disease in CML is relatively straightforward as all leukemic cells carry the BCR::ABL1 fusion oncogene, the product of the t(9;22) (q34;q11) reciprocal translocation. Once patients obtain a complete hematologic response, residual leukemic cells can be evaluated by reliable techniques in routine practice including conventional cytogenetics and molecular biology. Both cytogenetic and molecular MRD monitoring provide key prognostic information at the individual level and play a crucial role in patient management and decision making; however, regular assessment of MRD with karyotyping until a complete cytogenetic response (CCyR) is obtained tends to disappear in favor of molecular biology techniques. Molecular-based quantification of MRD is performed using the gold standard quantitative qPCR technique by amplifying peripheral blood *BCR::ABL1* transcripts and *ABL1* or *GUS* as control genes, with a $10^{-4.5}$ to 10^{-5} sensitivity.[21] To do so, it is of utmost importance to characterize the *BCR::ABL1* transcript type at diagnosis. Indeed, for most patients harboring major-type e14a2 or e13a2 BCR::ABL1 transcripts, standardized assays with results expressed on an international scale (IS) are used, but these assays are not designed for the rare patients with atypical transcripts.[22] BCR::ABL1 point mutations are a well-known mechanism of acquired resistance to tyrosine kinase inhibitors (TKIs) and can be detected and characterized using Sanger sequencing with a limit in sensitivity of 10%-20%.[23] NGS techniques tend to replace Sanger sequencing in routine practice because of the greater sensitivity, ability to detect low-level mutations (although with a risk of error), and to differentiate polyclonal mutations and compound mutants.[23]

In the next sections, we discuss the clinical relevance and medical decision making related to MRD testing in AML, ALL, and CML.

CLINICAL ROLE OF MRD IN AML

Monitoring of MRD in AML: Clinical Recommendations

In patients with AML with complete remission (CR) or CR with incomplete hematologic recovery prognosis can be further refined by MRD, with a median OS at 5 years of 68% in MRD-negative and 34% in MRD-positive patients.[5] The prognostic effect is well established for all MRD techniques in AML and different time points, for example, after two cycles of chemotherapy, at the end of treatment, before allogeneic hematopoietic cell transplantation (alloHCT), and during follow-up.[24] However, age and disease characteristics, such as genetic aberrations and treatment characteristics, influence the likelihood to achieve MRD negativity.[25] It is,

TABLE 1. Comparison of Measurable Residual Disease Techniques

Technique	Method	Sensitivity	Advantages	Limitations
Morphology	Identify and distinguish the presence of leukemic cells from nonmalignant cells in bone marrow using microscopy	5×10^{-2} (5%)	High availability	Low sensitivity
Cytogenetics (karyotyping)	Assessment of changes in the size, shape, structure, or no. of chromosomes (karyotype) in leukemia cells	1-5 $\times 10^{-2}$	High availability Needs a bone marrow aspiration and at least 20 metaphases Allows to detect ACAs (CML)	Low sensitivity
FISH	Cytogenetic method used to detect targeted abnormalities in leukemia genes or chromosomes	1×10^{-2}	Fast turnaround	Low sensitivity Not used to quantify MRD
Multicolor flow cytometry	Identify leukemic cells with a specific aberrant leukemia-associated phenotype using a panel of fluorochrome-conjugated antibodies	ALL: 10^{-4} to 10^{-5} (0.01%-0.001%) AML: 10^{-3} to 10^{-4} (0.1%-0.01%) CML: NA	Fast turnaround (<4 hours) Relatively low cost Provides information on antigen expression High availability	Variable sensitivity Technical laboratory expertise required No quality assurance and less standardized Requires fresh cells (<48 hours) Immunophenotypic shifts can lead to false-negative results Reduced sensitivity to detect MRD in blood samples Not established for monitoring during follow-up
qPCR for fusion genes	Quantification of *BCR-ABL* fusion gene RNA expression (p190 or p210 subtype)	ALL: 10^{-4} to 10^{-5} (0.01%-0.001%) AML: 10^{-5} (0.001%) CML: 10^{-5} (0.001%)	Standard primers used for specific fusion genes Fresh sample not needed High sensitivity Rapid turnaround Low cost	Absence of targets in >50% of patients Limited to *BCR-ABL1* in the United States Risk of contamination Not scalable for high volume Not standardized for minor transcripts
High-throughput NGS	Identify, quantify, and track unique disease-associated Ig mutations by sequencing IgH, IgK, and IgL rearrangements as well as TCR translocations, or somatic mutations in AML	ALL: 10^{-6} (0.0001%) AML: 10^{-4} (0.01%) CML: NA	Applicable to majority of patients Can identify, quantify, and track multiple unique clones and their evolution Only FDA-approved assay (for ALL) May be used in peripheral blood Fresh sample not needed Can scale up for high volume	High cost Requires diagnostic pretreatment sample Longer turnaround time than MFC (10-21 days) The analysis of NGS MRD data requires a bioinformatic pipeline Reliable markers not fully defined (AML) CHIP-associated variants not useful before alloHCT (AML) Limited throughput if targeted approach is chosen (AML)

NOTE. Sensitivity, advantages, and disadvantages are identical across the leukemia subtypes, unless otherwise indicated.

Abbreviations: ACA, additional cytogenetic abnormalities; alloHCT, allogeneic hematopoietic cell transplantation; CHIP, clonal hematopoiesis of indeterminate potential; CML, chronic myeloid leukemia; FDA, US Food and Drug Administration; FISH, fluorescence in situ hybridization; Ig, immunoglobulin; MFC, multiparameter flow cytometry; NA, not applicable for this leukemia type; NGS, next-generation sequencing; qPCR, quantitative polymerase chain reaction; TCR, T-cell receptor (adapted from [1,7-9]).

therefore, important to evaluate the prognostic value of MRD in the context of the current ELN risk classification, which specifies the MRD technology, time point, tissue, and cutoff for the use of MRD as a prognostic biomarker in patients with AML (Fig 1).[26] Importantly, a large retrospective study confirmed the prognostic importance of MFC-MRD in each of the three ELN risk groups.[27]

MRD results are frequently requested by clinicians as a prognostic marker; however, the predictive role of MRD in selecting treatment options for patients with AML is just evolving. The most important clinical question currently is whether MRD can help assigning patients to chemotherapy consolidation or alloHCT. This question was first addressed in an Italian study, where MFC-MRD guided the transplant

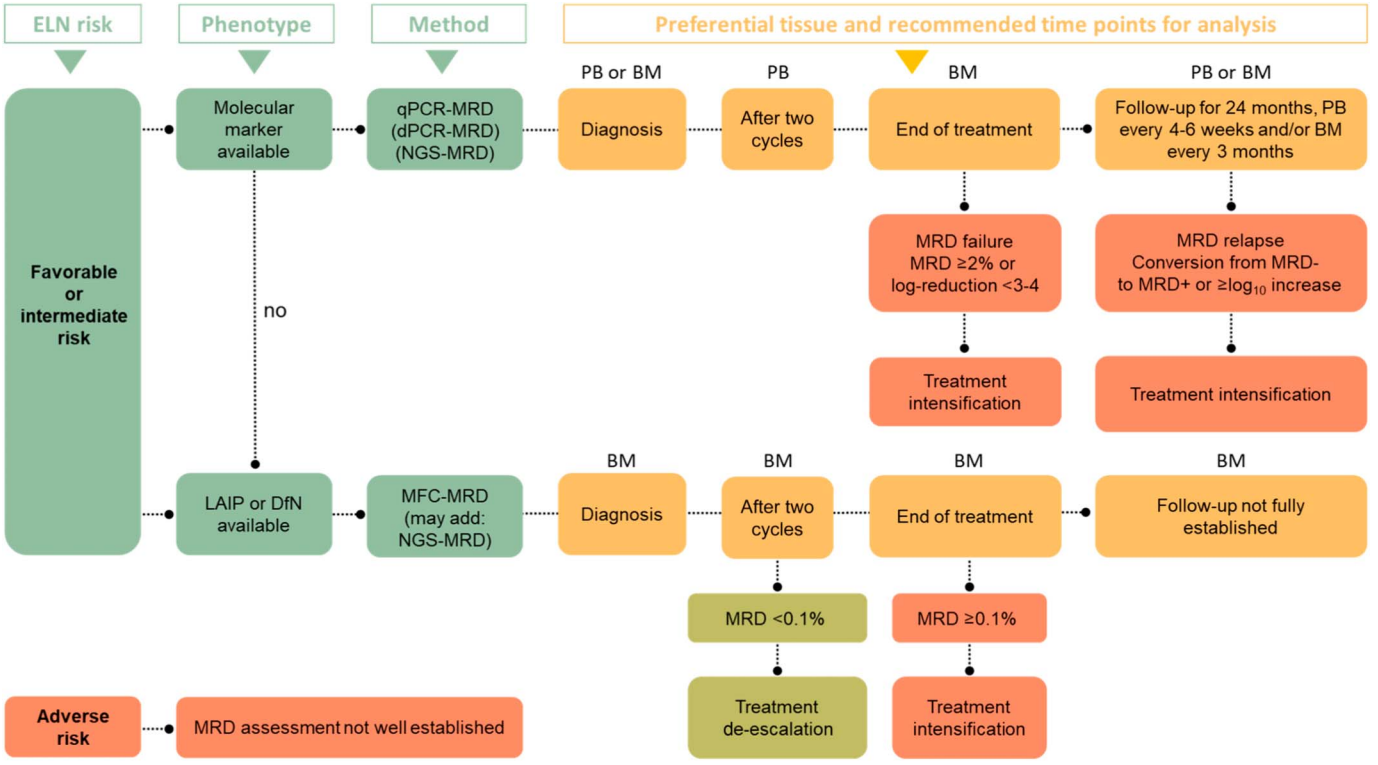

FIG 1. Incorporation of MRD quantification in standard care for AML. BM, bone marrow; DfN, different-from-normal phenotype; dPCR, digital polymerase chain reaction; ELN, European LeukemiaNet; LAIP, leukemia-associated immunophenotype; MFC, multiparametric flow cytometry; MRD, measurable residual disease; NGS, next-generation sequencing; PB, peripheral blood; qPCR, quantitative polymerase chain reaction.

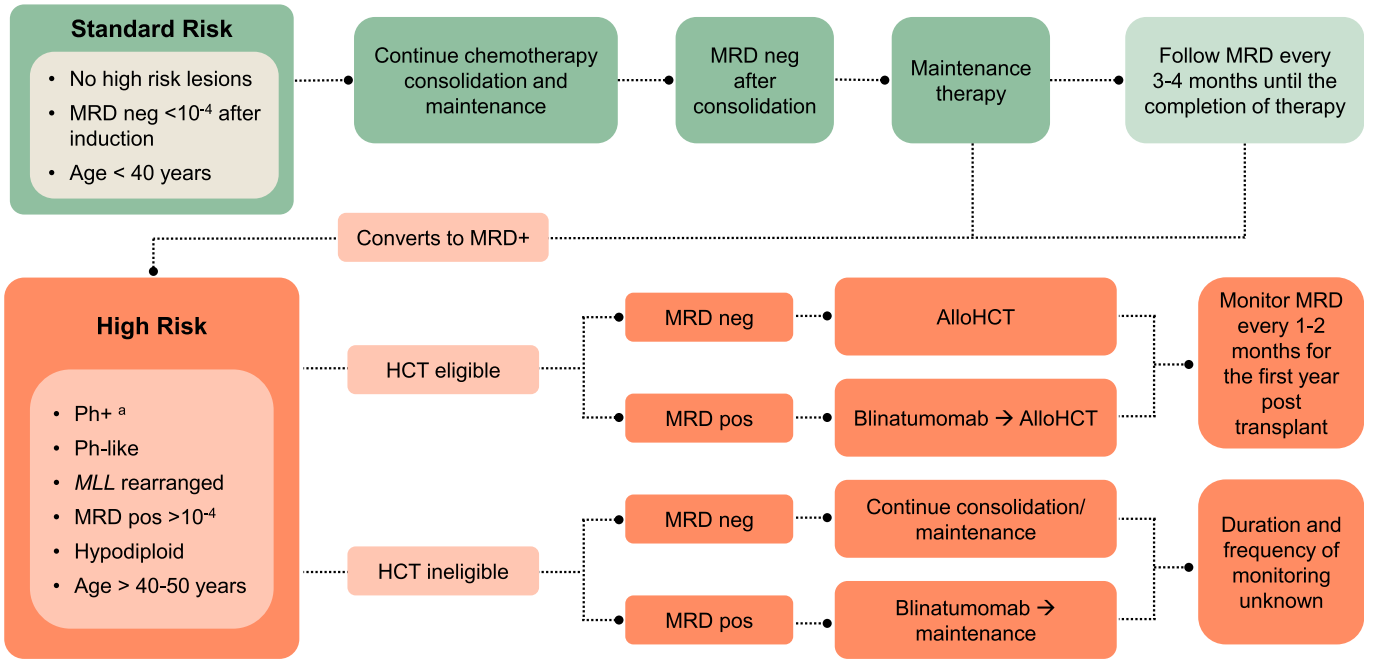

FIG 2. Incorporation of MRD quantification in standard care for ALL. alloHCT, allogeneic HCT; HCT, hematopoietic cell transplantation; MRD, measurable residual disease; neg, negative; pos, positive. [a]Possibly no longer high risk with emerging clinical data.

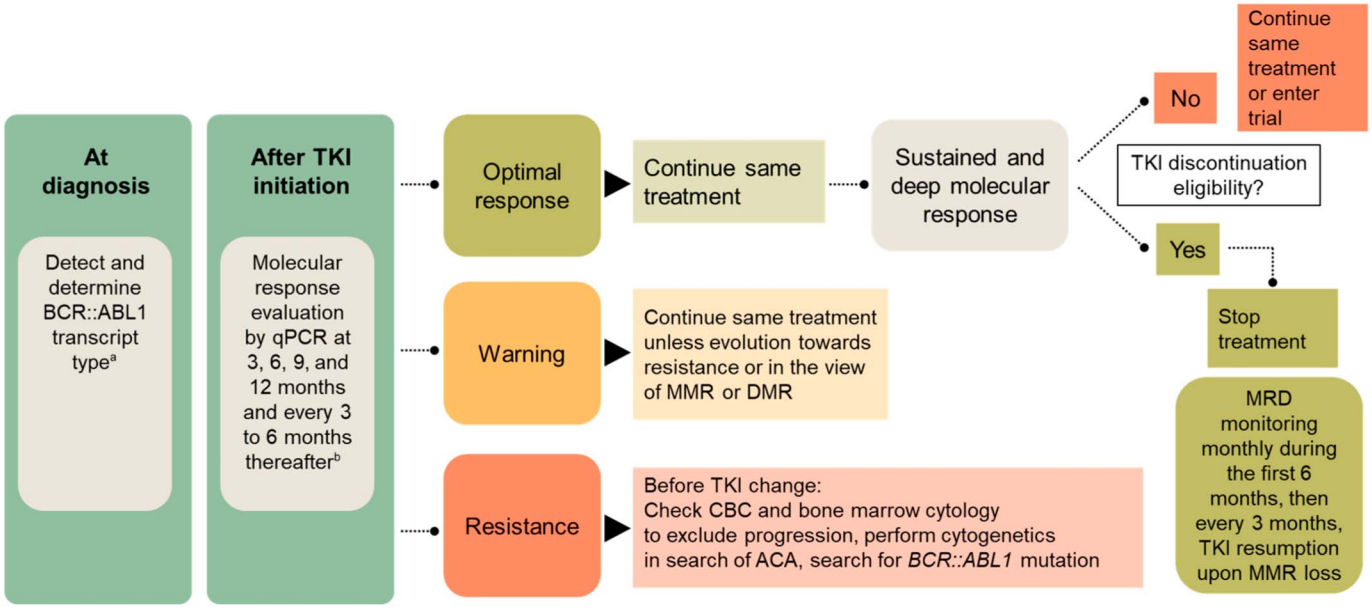

FIG 3. Incorporation of MRD quantification in standard care for CML. ACA, additional chromosomal abnormality; DMR, deep molecular response, defined as normalized *BCR-ABL/ABL1* ratio <0.01%; MMR, major molecular response, defined as normalized *BCR-ABL/ABL1* ratio <0.1%; qPCR, quantitative polymerase chain reaction; TKI, tyrosine kinase inhibitor. [a]Precise quantification by qPCR not mandatory except if halving times planned to be measured in the setting of a research approach. In this situation, use *GUS* or *BCR* as a control gene until MMR is reached, then *ABL1*. [b]Measured in peripheral blood.

decision in NCCN-defined intermediate risk patients with AML.[28] MRD-negative patients were recommended to undergo consolidation with chemotherapy or autologous transplantation while MRD-positive patients were recommended to undergo alloHCT. Disease-free and OS were identical among MRD-negative and MRD-positive patients, suggesting that the risk-adapted consolidation approach overcame the negative prognostic effect of MRD on the one hand and could spare alloHCT-associated toxicity for a significant number of patients on the other hand. A similar risk adapted consolidation approach was also applied in the HOVON 132 study.[29] The study showed that MRD no longer had a prognostic effect in the ELN intermediate-risk group and that alloHCT could be spared in a significant number of MRD-negative patients.[30] Outcome in MRD-negative patients, who were consolidated with high-dose chemotherapy and autologous transplantation, was similar to outcome of MRD-positive patients, who underwent alloHCT.

A recent study by Zhang et al[27] investigated the role of alloHCT in 769 patients who achieved CR within two cycles of chemotherapy in the context of ELN risk groups. In the ELN-favorable and intermediate-risk groups, MRD-negative patients did not benefit from transplantation. However, MRD-positive patients had a highly significant survival benefit with alloHCT. MFC-MRD in the adverse risk group was not prognostic when assessed after two cycles of chemotherapy, and OS was improved in patients undergoing alloHCT independent of MRD status. These data led to the ELN MRD recommendation that MFC-MRD measured after two cycles of standard induction chemotherapy in CR patients is a predictive biomarker that can guide the consolidation strategy (Fig 1). However, a prospective study proving this approach is lacking, and to our knowledge, no data comparing an MRD-guided with an MRD-unguided approach are currently available.

What is the Best MRD Conversion Strategy in Patients With AML?

MRD-positive patients who undergo alloHCT have a high relapse rate and shorter OS than MRD-negative patients. The question has been raised whether MRD-positive patients should be converted to MRD-negative with additional treatment before undergoing alloHCT. Emerging data are helping to clarify this issue. Paras et al[31] published a large retrospective study including 810 patients undergoing alloHCT in CR1 or CR2. MRD was assessed with MFC-MRD before and after alloHCT. Sequential MRD assessment revealed that of the 161 MRD-positive patients before alloHCT, 118 became MRD-negative after HCT, corresponding to a 73% MRD conversion rate by alloHCT. Patients who were MRD-negative before and after alloHCT had the lowest relapse incidence and highest OS. Importantly, MRD-positive patients who converted to MRD-negative had a significantly lower relapse incidence than patients who were MRD-positive before and after alloHCT and also had a

significantly longer OS. Thus, alloHCT currently is the only MRD conversion treatment for which a survival benefit has been shown. A MRD conversion rate of 60%-74% by alloHCT, including an improved OS, was also found when MRD was assessed with NGS.[32,33]

MRD conversion has also been investigated outside the setting of alloHCT. A prospective phase II study treated primarily *NPM1*-mutated patients with rising MRD with venetoclax and low-dose cytarabine. MRD response was achieved in 69% with 54% becoming CR MRD-negative. After a median follow-up of 18 months, the 2-year OS was 72.6%, and the EFS was 55.4%.[34] A retrospective study by Othman et al[35] evaluated the conversion efficacy of FLT3 inhibitors in patients with molecular failure. Of 49 evaluable patients treated with one of the available FLT3 inhibitors, 63% responded, of whom 45% achieved complete response. The molecular response (MR) rate was 93% in patients who had received previous alloHCT compared with 50% in patients who did not. After a median follow-up of 24.2 months, 2-year OS was 79%. In summary, the MRD conversion rate appears similar within the respective target populations with direct alloHCT in MRD-positive patients and patients with MRD relapse who receive either venetoclax/azacitidine or FLT3 inhibitors. Currently, it seems reasonable to proceed with alloHCT directly in MRD-positive patients and treat with FLT3 inhibitors after transplantation (in *FLT3*-mutated patients) while the results of the ongoing venetoclax/azacitidine maintenance study after alloHCT should be awaited, before such an approach can be routinely used after alloHCT for MRD-positive patients with AML. Few patients may be MRD negative after induction chemotherapy and turn MRD positive directly before alloHCT. These patients very likely have aggressive disease, and alternative treatments before alloHCT may be considered.

MRD in Patients With AML Not Eligible for Intensive Chemotherapy

Several studies have recently evaluated the prognostic effect of MRD in patients with nonintensively treated AML. Randomized studies evaluating venetoclax and cladribine in combination with azacitidine or low-dose cytarabine evaluated MRD most often with MFC-MRD. Sixty percent to seventy-one percent of patients were MRD positive when evaluated with MFC-MRD while 71%-100% of patients were MRD-positive using molecular methods.[36-46] MRD proved to be highly prognostic for relapse-free survival (RFS) and OS. The median RFS was 16.2 months in MRD-negative patients compared with 7.05 months in MRD-positive patients. The median OS was 26.2 months in MRD-negative patients compared with 13.8 months in MRD-positive patients. Appropriate time points for MRD assessment and potential impact for treatment guidance are currently being evaluated. In the Viale-A trial, 25% of all MRD-negative patients were identified after the first cycle, 27% after the fourth cycle, 27% after the seventh cycle, and 21% thereafter.[36] However, patients treated with 10 days of decitabine and venetoclax who were MRD positive 2 months after the start of treatment had a median EFS of only 5.8 months and a median OS of 7.1 months.[37] Thus, patients who are MRD positive after four to seven cycles of a hypomethylating agent combined with venetoclax seem to comprise a patient population in which additional treatment strategies should be developed to decrease the relapse risk.

CLINICAL ROLE OF MRD IN ALL

Predictive Value of MRD in Patients With ALL

MRD is a strong predictor of outcome and relapse risk in pediatric and adult ALL.[4,47] In a recent meta-analysis including 39 studies with more than 13,000 patients with ALL from both the adult and pediatric populations, MRD was uniformly associated with improved EFS and OS in both groups.[48] A cross-sectional physician survey on the use of MRD testing in adult and pediatric ALL showed that the use of MRD is standard protocol for 93% of pediatric physicians versus 53% of adult physicians.[49] Short et al evaluated the clinical impact of highly sensitive NGS in a medium-sized single-center study (74 patients). They demonstrated that many patients who are MRD negative by MFC still have clinically significant MRD that is detectable with ultrasensitive NGS assays.[50] In this cohort, all patients who were MRD positive by MFC were also MRD positive by NGS. However, 46% of MRD-negative samples by MFC were MRD positive by NGS. None of the MRD-negative patients by NGS relapsed after induction.[50] The importance of ultrasensitive NGS MRD monitoring was confirmed in a larger multicenter cohort of adult patients with ALL who underwent HCT at Stanford University or Oregon Health & Science University (n = 157).[17] Liang et al demonstrated that detectable pre-HCT MRD, even at a low level of 10^{-6} and any detectable post-HCT MRD, increased the risk of post-HCT relapse. Patients with undetectable pre-HCT MRD who continued to have undetectable MRD post-HCT through the first 2 years after transplant have excellent outcomes (<10% likelihood of relapse).[17] These findings are consistent with previous work in pediatric populations. Sekiya et al[51] previously found that NGS-based monitoring of MRD in pediatric B-ALL predicts leukemia-free survival. Another study by Wood et al[52] showed that MRD detection by NGS improves risk stratification for pediatric B-ALL. Gokbuget et al[53] used MRD-directed treatment with blinatumomab administered for $>10^{-3}$ MRD after three blocks of intensive chemotherapy and demonstrated that 80% of patients achieved MRD $<10^{-4}$ after one cycle, and median OS was not reached in the subset of patients who attained MRD negativity.

MRD measurements are also predictive of relapse in patients with B-ALL undergoing chimeric antigen receptor T-cell therapy. In pediatric and young adult patients treated with tisagenlecleucel, failure to achieve MRD negativity by day 28 or 3 months was associated with poor outcomes, with patients relapsing before 3 months. Sensitivity of MRD assessment was also predictive of outcomes. The risk of relapse was 50%, 31%, and 0% for MRD negativity at the level of 10^{-4}, 10^{-6}, and below 10^{-6}, respectively.[4] Ongoing studies are evaluating the prognostic significance of MRD positivity after treatment of adult patients with brexucabtagene (eg, NCT02614066).

Monitoring of MRD in ALL: Clinical Recommendations

Figure 2 illustrates how MRD quantification can be incorporated in standard care for patients with ALL. We recommend identification of patient-specific immunophenotypes or clonotypes for MRD tracking at baseline, then following MRD after induction, consolidation and delayed intensification, and then every 3-6 months throughout the course of maintenance therapy.[8] For patients undergoing alloHCT, we recommend obtaining a pretransplant MRD assessmen, and then serial monitoring via the blood or bone marrow within the first 45 days after transplant and then every 1-2 months for 1 year post-transplant.[17] The high sensitivity of NGS allows for MRD quantification in peripheral blood, and this appears to be an adequate alternative and allows for more frequent monitoring than frequent bone marrow assessments in the post-transplant setting.[20] Patients with standard-risk ALL who are eligible for treatment with a pediatric-inspired regimen and MRD negative at the level of $<10^{--4}$ should continue chemotherapy, consolidation, and maintenance. If these patients convert to MRD positivity, they should be treated similarly to patients with high-risk ALL. Patients with high-risk ALL (Ph+, Ph-like, MLL rearranged, hypodiploid, early T-cell precursor (ETP)-ALL, MRD positivity $>10^{-4}$) in CR should be assessed for HCT eligibility. HCT-eligible patients who are MRD positive should receive blinatumomab before transplant while blinatumomab is not required for MRD-negative patients. Of note, the use of blinatumomab to clear pretransplant MRD has not been studied in a randomized clinical trial, and it is unlikely that such a trial will ever be undertaken. High-risk MRD-negative patients who are HCT ineligible should continue consolidation and maintenance. High-risk MRD-positive patients who are ineligible for HCT should receive blinatumomab and then continue with maintenance. At this time, there are no agents approved to treat MRD in patients with T-cell ALL, and this remains an unmet clinical need. In adults with Ph+ ALL, it remains unclear whether MRD detected by BCR-ABL qPCR or NGS should be used to monitor disease. Measuring MRD via both NGS and BCR-ABL qPCR may help identify patients who are at very low risk for relapse or identify those at higher risk for progressive disease. There is a subset of patients who are MRD negative by NGS but have ongoing BCR-ABL positivity, but the clinical significance of this group is unclear.[54,55] Studies are underway to determine the relative specificity of NGS versus BCR-ABL qPCR in adults with Ph+ ALL and the prognostic implications of discrepant MRD results.[56]

It is important to note that MRD should be evaluated within the context of specific genotypes and clonotypes. For example, Jeha et al[57] examined the prognostic implications of leukemic subtypes in pediatric ALL by using genomic analysis and MRD assessments during remission induction. Their results suggest that both genomic analyses and MRD measurements are required to accurately stratify children with ALL into risk groups. Liang et al[58] recently examined the prognostic significance of various clonotypes (eg, IgH *v* Ig/Ig) detected by NGS MRD in adult B-cell ALL. They demonstrated that detection of IgH clonotypes after HCT, but not Ig/Ig clonotypes, is associated with increased risk for relapse.

CLINICAL ROLE OF MRD IN CML

Clinical and Prognostic Significance of MRD in CML

In the early 2000s, imatinib, the first TKI to specifically target activity of the BCR::ABL1 oncoprotein through direct competitive inhibition of ATP binding, was introduced into the clinic to treat patients with CML. During imatinib development, the drug was able to transform this fatal leukemia into a disease compatible with a near-to-normal lifespan providing early and durable Philadelphia chromosome (Ph1) negativity on bone marrow cell metaphases, highlighting the key prognostic value of cytogenetic responses on PFS in the TKI era.[59] Using more sensitive MRD detection techniques such as quantification of peripheral blood *BCR::ABL1* transcripts by qPCR assays, it was also discovered that most patients in CCyR retained detectable leukemic cells but over a wide range with varying clinical significance. Patients with highest long-term PFS rates were those in CCyR together with a 3-log reduction in *BCR::ABL1* transcript levels. Landmark analyses demonstrated a robust association between the degree of *BCR::ABL1* transcript decline on-therapy and long-term clinical outcome, supporting the use of time-dependent molecular measures to determine response to therapy.[60] Since then, qPCR assays have improved in sensitivity, reliability, and reproducibility, and international efforts have been made toward standardization of techniques.[21] Deep molecular responses (DMRs) at or below the 10^{-4} and down to the 10^{-5} level have been accurately defined given their importance for TKI discontinuation decision making in the view of treatment-free remission (TFR).[61] MRD levels after TKI discontinuation is used to predict and define molecular relapse which

triggers TKI resumption.[62] The therapeutic arsenal against CML now comprises the first-generation TKI imatinib, three second-generation ATP-competitive TKIs (bosutinib, dasatinib, and nilotinib), one third-generation TKI ponatinib, and one selective allosteric inhibitor asciminib. This arsenal of orally targeted agents is essential to meet ambitious treatment goals for patients diagnosed with chronic phase (CP)-CML.[63]

Monitoring of MRD in CML: Clinical Recommendations

Both the ELN and the NCCN recommend assessing MRs every 3 months (Fig 3).[63,64] *BCR::ABL1* ≤10% (MR1) corresponds to a 1-log reduction of a standardized leukemic load baseline. *BCR::ABL1* ≤1% (MR2) is a molecular equivalent of a CCyR and corresponds to a 2-log reduction in leukemic load. *BCR::ABL1* ≤0.1% (MMR or MR3) corresponds to a 3-log reduction in leukemic burden. DMR includes MR4 (*BCR::ABL1* ≤0.01%), MR4.5 (*BCR::ABL1* ≤0.0032%), and MR5 (*BCR::ABL1* ≤0.0001%). MR is defined at specific time points and divided into three categories: optimal, warning, and resistance, with a specific focus on the first 3 to 12 months after initiation of TKI treatment.[63,64] Optimal responders do not require treatment modification unless they qualify for TKI discontinuation. Resistance mandates a change in therapy guided by results from *BCR::ABL1* kinase domain (KD) mutation analysis. Warning corresponds to a situation where *BCR::ABL1* transcripts decrease at or below the 1% IS level after 1 year of treatment, but MMR is not achieved. Overtime, the warning category may remain as such or evolve toward either resistance or an optimal response with a longer treatment duration. However, the likelihood of reaching DMR levels in the absence of any TKI treatment modification is low.[65]

Long-term TFR with continued optimal MR off-therapy is currently the most optimal benefit of CML TKI treatment, and a sustained DMR is one of the prerequisites for TKI discontinuation.[66] ELN minimal criteria for safely stopping TKIs include (1) CML in first chronic phase (CP); (2) TKI taken first or second line providing that treatment change was driven by intolerance; (3) at least 5 years of treatment with the first-generation TKI imatinib or 4 years with second-generation TKIs dasatinib, nilotinib or bosutinib; and (4) at least 2 years of sustained MR4 or better.[63] NCCN selection criteria for TKI discontinuation are less stringent: At least 3 years of treatment are requested, including at least 2 years of sustained MR4 or better.[64] Patients qualifying for TKI discontinuation have a long-term TFR chance of 50%, but prolonged DMR is associated with better TFR probabilities.[67] On TKI discontinuation, MRD monitoring is key as relapse is defined as a loss of MMR, which triggers TKI resumption. Once TKIs are discontinued, it is recommended to monitor MRs monthly during the first 6-12 months as the majority of molecular relapses (about 85%) occur within this time frame and to continue subsequent monitoring every 3 months.[66]

WHAT PATIENTS NEED TO KNOW ABOUT MRD

MRD testing is common, but not universal. Provider education on appropriate testing and MRD quantification is needed as well as improved access to MRD testing. The main barriers to MRD assessment for patients are cost, insurance approval, and the proximity to tertiary care. Consensus is lacking on the timing of testing during treatment, and serial measurements can help with ambiguity in MRD test results. The turnaround time for the three major MRD technologies is quite different. MFC-MRD is usually assessed on the same day the bone marrow sample is collected. qPCR can be done from frozen tissue material and therefore typically is stored for some days until sufficient samples are collected to run an MRD assay. NGS also usually uses frozen tissue samples, and current methods require time for sample and library preparation, high coverage sequencing, bioinformatic medical analysis, and reporting. Thus, results are available most quickly with MFC, after a few days with qPCR, and after 2-3 weeks with NGS.

Patients should be informed that MRD is one of the several prognostic markers and contributes to decision making in concert with other prognostic information. Patients with AML should understand that an appropriate MRD marker may not be available for all patients, that the MRD technology varies depending on the type of AML, and that the MRD markers may change over time. After two cycles of treatment, MRD may be used to decrease treatment intensity, whereas at the end of treatment and during follow-up, MRD results may be used to increase treatment intensity. Patients with ALL should be aware of the major impact of MRD measurements on clinical decision making. Changes in treatment regimens, the decision to proceed with allogeneic stem-cell transplant, and how much therapy to give before stem-cell transplant are all based on the presence or absence of MRD. Patients with CML should understand that MRD reflects the sensitivity of the leukemic cells to TKIs and influences treatment decisions and thus the importance of a high-quality MRD monitoring on a regular basis. However, patients should be informed that intrinsic variations of the qPCR assay may be devoid of biological and clinical relevance as a minor increase in *BCR::ABL1* transcripts because of technical aspects may be a source of anxiety.

PERSPECTIVES IN MRD MONITORING

MRD monitoring in ALL, particularly in pediatric patients, has long been established as part of standard of care. It is well understood that residual MRD is a poor prognostic marker, and blinatumomab has become the first FDA-

approved agent to treat MRD. Clinical trials are underway investigating the usage of other agents for the treatment of MRD, with the end point being MRD negativity. Positive results could lead to more approvals for agents to target MRD, including inotuzumab for B-ALL, daratumumab for T-ALL, and ponatinib for Ph+ ALL. As we gain additional evidence that MRD negativity correlates with improved outcomes, MRD is more frequently being adapted as a surrogate end point for clinical trials, which could speed the approval process for novel agents. One area of unmet need in MRD monitoring for ALL is the detection of isolated extramedullary or CNS disease. Isolated extramedullary relapse has been found to be a major mechanism of blinatumomab failure,[68] and isolated CNS relapse is a well-known phenomenon in ALL. It remains unknown whether blood-based MRD assessments, which rely on circulating leukemia cells, can detect isolated extramedullary or isolated CNS disease. New techniques for MRD monitoring include measuring cell-free DNA and DNA methylation profiling. These methods may overcome the limitations of using cell-based assays to follow extramedullary-only disease, and preliminary evidence suggests that these assays are able to detect CNS disease through blood measurements.[69]

Although standardization of *BCR::ABL1* monitoring and ALL-MRD is well established, standardization of MRD assessment in AML is one of the major tasks for the next few years. New methods of MRD quantification are currently emerging for all leukemias.[70] Transcript monitoring by digital PCR offers a greater precision than qPCR and can also be used to detect mutations in the target genes such as the *BCR::ABL1* KD. DNA PCR can be standardized; it offers a greater sensitivity than RNA PCR (up to 10^{-6}) and enables leukemic cell detection, in which the target transcript is transcriptionally silent. However, it requires the sequencing of breakpoints and primer design on an individual basis. There are several attempts to identify residual leukemic stem cells (LSCs) by flow cytometry, but there may be variations in surface markers among individuals, and to our knowledge, none of current candidate markers have a 100% specificity. Spectral flow cytometry allows evaluation of many more antigens than conventional flow cytometry, possibly leading to robust, reproducible panels that require fewer cells for analysis. Automation of flow cytometry analysis is another critical goal for the future to improve reproducibility of AML MRD. Single-cell analyses may help better understand resistance and LSC persistence and heterogeneity. To what extent these new methods will help better predict outcomes is under evaluation.

CONCLUSION

In summary, MRD has evolved to become a critical diagnostic method that predicts disease progression and is increasingly used as an important end point in evaluating novel treatments for patients with leukemia. The science behind MRD monitoring continues to evolve, with new and more sensitive assays actively being investigated.

The Times, They Are A-Changing: The Impact of Next-Generation Sequencing on Diagnosis, Classification, and Prognostication of Myeloid Malignancies With Focus on Myelodysplastic Syndrome, AML, and Germline Predisposition

Sandeep Gurbuxani, MBBS, PhD[1]; Michael J. Hochman, MD[2]; Amy E. DeZern, MD, MHS[2]; and Akiko Shimamura, MD, PhD[3]

overview

Myeloid malignancies are a manifestation of clonal expansion of hematopoietic cells driven by somatic genetic alterations that may arise in a potential background of deleterious germline variants. As next-generation sequencing technology has become more accessible, real-world experience has allowed integration of molecular genomic data with morphology, immunophenotype, and conventional cytogenetics to refine our understanding of myeloid malignancies. This has prompted revisions in the classification and the prognostication schema of myeloid malignancies and germline predisposition to hematologic malignancies. This review provides an overview of significant changes in the recently published classifications of AML and myelodysplastic syndrome, emerging prognostic scoring, and the role of germline deleterious variants in predisposing to MDS and AML.

INTRODUCTION

Dr Janet Rowley first described a series of chromosomal abnormalities associated with specific hematologic malignancies in the 1970s laying the groundwork for establishing myeloid malignancies as a genetic disease.[1] However, it was not until 2001 when the third edition of the WHO classification incorporated karyotype as defining criteria for subtype of AML,[2] moving away for the first time from the morphologically defined diagnoses laid out in the French American and British (FAB) classification. In contrast to this slow pace of incorporating genomic data into clinical diagnosis, driven by easy access to next-generation sequencing (NGS) technology, the past two decades have seen almost revolutionary progress in incorporating genomics into disease diagnosis, classification, and risk stratification.[3-5] Furthermore, as our understanding of the pathogenesis of myelodysplastic syndrome (MDS) and other myeloid malignancies continues to improve, we now know that there are germline variants that determine not just predisposition to hematologic malignancies but also our choice of initial therapy and decision to transplant. The review provides an overview of how the ever-expanding array of genomic data affect classification of myeloid malignancies, risk stratification of MDS, and evaluation for germline predisposition to hematologic malignancies.

UNDERSTANDING THE 2022 WHO AND INTERNATIONAL CONSENSUS CLASSIFICATION OF MYELOID NEOPLASMS

For reasons outside the scope of discussion within this manuscript, two different updates were published on the classification of hematopoietic tumors. The International Consensus Classification (ICC) retained the process of seeking input from the Clinical Advisory Committee (CAC) and published the outline of its classification in the journal *Blood* in 2022.[6] A significant proportion of the ICC authors have contributed to the previous WHO classifications. Since the publication of the outline in *Blood*, additional and more detailed manuscripts on specific categories of myeloid malignancies and leukemias have been published by the ICC authors. In contrast, the WHO identified editorial board members who in turn formed a multidisciplinary team of authors to generate the fifth edition of the WHO classification (WHO-5). An outline of WHO-5 was published in 2022 in the journal *Leukemia*.[7] A beta version of the blue book with additional details is available online; publication of the hard copy of the monograph is imminent. There is minimal overlap between the authors who contributed to the previous editions of WHO and WHO-5.

Simultaneous publication of two different classifications has understandably created much confusion and

Author affiliations and support information (if applicable) appear at the end of this article.

PRACTICAL APPLICATIONS

- Genomic characterization determines diagnosis, classification, and prognostication of the myeloid malignancies myelodysplastic syndrome (MDS) and AML.
- Recognizing genetic lesions as invariable determinants of disease biology allows for a diagnosis of specific types of myeloid malignancies independent of traditional morphologic criteria such as presence of ring sideroblasts (*SF3B1* mutation), dysplasia (chronic myelomonocytic leukemia), or specific blast counts (AML with defining cytogenetic abnormalities). More commonly evaluated genetic lesions are listed in Table 1.
- Multiple models have shown that incorporation of molecular data generates prognostic scores that outperform older models such as International Prognostic Scoring System and revised IPSS in predicting disease progression in MDS. It is, therefore, recommended that molecular data should be integrated into decision making for MDS clinical care including eligibility for clinical trials.
- It is now recognized that germline predisposition to myeloid malignancies may exist independent of any syndromic presentation. Testing for germline variants should be performed on nonhematopoietic tissue using specifically designed panels on the basis of clinical findings (including a thorough family history).
- Identifying germline variants has a significant impact on decisions regarding therapy including donor selection for potential hematopoietic stem-cell transplant.

consternation among hematologists, pathologists, and oncologists alike. Fortunately, despite the many differences between the two classifications, there are common themes that provide the rationale for the most significant differences between WHO 2016 and both the recent ICC and WHO-5 classifications. Table 2 provides the overarching classification of myeloid malignancies. We focus specifically on changes in the classification of chronic myelomonocytic leukemia (CMML), MDS, and AML. Additional changes were also seen in myeloproliferative diseases and lymphoid disease which are beyond the scope of this article.

CMML

Tremendous progress has been made in teasing out the biology of CMML in the past decade. Whole-genome sequencing coupled with single-cell analysis demonstrates linear accumulation of somatic variants in different classes of genes starting with epigenetic (*TET2*, *DNMT3A*, *ASXL1*, and *EZH2*), followed by RNA splicing (*SRSF2*, *SF3B1*, *U2AF1*, and *ZRSR2*) and finally cell signaling (*NRAS*, *KRAS*, *CBL or JAK2*). A smaller proportion of patients will also have mutation in transcription factors (*RUNX1*) and nucleosome assembly (*SETBP1*).[8,9] Two themes emerge from this treasure trove of molecular data in CMML—(1) more than 90% of the patients will have a demonstrable clonal mutation in their hematopoietic stem cells and (2) the complement of mutation will determine the dysplastic versus proliferative phenotype of CMML in any given patient. Thus, both the ICC and WHO-5 integrate genetic mutations into the diagnostic criteria for CMML. Furthermore, when a mutation is present, a diagnosis of CMML can now be made with a lower monocyte count (0.5 to $<1 \times 10^9$/L, oligomonocytic), provided the relative monocyte count is >10%. The ICC requires the variant allele frequency (VAF) of the somatic mutations to be >10%. In as much as somatic mutations are part of the diagnostic criteria for CMML, WHO-5 provides recommendations on minimal genes to be included in the workup for possible CMML without specifying a VAF threshold to establish clonality. Finally, both ICC and WHO-5 recognize that the more myeloproliferative CMML presenting with WBC $>13 \times 10^9$/L are enriched for mutations in the signaling pathways (*NRAS*, *KRAS*, *CBL*, *or JAK2*).[9] WHO-5 specifically incorporates CMML-MD and CMML-MP subtypes into the classification. Although CMML-MP is discussed in the ICC monograph, there is no recommendation on how to include this in the diagnosis topline. In contrast, and not related to the presence of genetic mutations, both classifications recognize the lack of reproducibility and clinical significance for the category of CMML-0 defined by <2% blasts in peripheral blood and <5% blasts in the bone marrow. Both classifications now eliminate this category, subsuming this category into CMML-1 (<5% blasts in the peripheral blood and <10% in the bone marrow). Finally, both classifications acknowledge challenges associated with presence of *NPM1* mutations in cases that previously met the criteria for a diagnosis of CMML.[10] However, it is likely that most of these patients will get an up-front diagnosis of AML on the basis of the lowered blast threshold in both classifications.

Clonal Cytopenias of Undetermined Significance

Clonal hematopoiesis (CH) is defined by the acquisition of somatic mutations in hematopoietic stem and progenitor cells in healthy individuals.[11] ICC and WHO-5 identify two precursor conditions, clonal hematopoiesis of indeterminate potential (CHIP) and clonal cytopenias of unknown significance (CCUS), that have been formally defined. CHIP is defined as CH mutations that occur in leukemia driver genes with VAF ≥2% in patients without cytopenias and who

TABLE 1. Genetic Variants Associated With Cytopenias, MDS, MDS/MPN, and AML

Abbreviations: FISH, fluorescent in situ hybridization; ICC, International Consensus Classification; MDS, myelodysplastic syndrome; MPN, myeloproliferative neoplasm; NGS, next-generation sequencing.

[a]Mutations in *CEBPA* and *NPM1* define specific entities in ICC and WHO classifications. Additional details on the techniques and specific timing for performing the NGS assays can be found in the study of Duncavage et al.[47]

do not otherwise meet diagnostic criteria for a myeloid neoplasm (MN); when CHIP is accompanied by unexplained cytopenias, it is termed CCUS.[6,7,12]

Myelodysplastic Syndrome

Both ICC and WHO-5[6,7] have made significant changes to the classification of MDS (Table 3). The ICC retains the historical nomenclature of MDS and excess blasts (EBs). In contrast, WHO-5 transitions to the term myelodysplastic neoplasms (abbreviation MDS is retained) and increased blasts instead of EBs used in the previous classifications. Both classifications recognize CH as the foundation for MDS contributing to a spectrum of hematopoietic abnormalities ranging from CCUS to MDS. It should be pointed out that both classifications define CCUS to include not just cytopenias associated with somatic mutations with VAF >2% but also several karyotype abnormalities that would have resulted in the diagnosis of MDS, unclassifiable in WHO-4 R in the absence of morphologic dysplasia. Both classifications recognize MDS-SF3B1 mutation as a genetically defined entity with comparable diagnostic criteria. However, there is divergence in how ICC and WHO-5 approach the diagnosis of MDS in the presence of >15% ring sideroblasts without *SF3B1* mutation. In ICC, such cases would be diagnosed as MDS, NOS, provided additional criteria for diagnosis of MDS are met. In contrast, WHO-5 retains the category of MDS with low blasts and ring sideroblasts to allow inclusion of MDS cases harboring driver mutations in other RNA splicing components.[13] The impact that this might have on a small subset of patients who would potentially receive specific therapy with compounds such as luspatercept-aamt remains to be seen. Both classifications also recognize the significance of multihit TP53 alterations to identify a specific category of high-risk MDS[14] albeit with comparable but not identical definitions for identifying biallelic *TP53* mutations. A morphologic diagnosis and subclassification of MDS can be made on the basis of the blast count and the number of lineages affected by dysplasia (Table 3). Of note, although both ICC and WHO-5 have philosophical agreement on MDS and AML representing a continuum when bone marrow blast count is ≥10% (or peripheral blood blast count ≥5%), there is a difference in how MDS would be formally classified by ICC and WHO-5. In ICC, such disease in adults would be classified as MDS/AML to allow eligibility for both MDS and AML trials[15] and in WHO-5 as MDS-IB2 in the absence of fibrosis or MDS-F if there is increased bone marrow fibrosis. Of note, as written in the current beta version of WHO-5, MDS-IB1 and MDS-IB2 are subsumed into a single diagnosis of MDS-F irrespective of the peripheral blood and bone marrow blast count. Although this difference in nomenclature is likely to cause much anguish, it should be noted that a diagnosis of AML can be made if an AML defining genetic abnormality is present without reaching a threshold of 20% blasts in either classification.

TABLE 2. ICC and WHO-5 Classification of Myeloid Neoplasms

ICC	WHO
Myeloproliferative neoplasms	Myeloproliferative neoplasms includes JMML
Myeloid/lymphoid neoplasms with eosinophilia and tyrosine kinase gene fusions	Myeloid/lymphoid neoplasms with eosinophilia and defining gene rearrangement
Mastocytosis	Mastocytosis
Myelodysplastic/myeloproliferative neoplasm	Myelodysplastic/myeloproliferative neoplasms
Premalignant clonal cytopenias and myelodysplastic syndrome	Myeloid precursor lesions, clonal hematopoiesis
	Myelodysplastic neoplasms (retained abbr MDS)
Pediatric and/or germline mutation–associated disorders	Myelodysplastic neoplasms of childhood (specific category in MDS)
	Myeloid neoplasms associated with germline predisposition (specific category in myeloid neoplasms and proliferations associated with antecedent or predisposing conditions)
AMLs	AML
Myeloid proliferations associated with Down syndrome	Myeloid proliferations associated with Down syndrome (specific category in myeloid neoplasms and proliferations associated with antecedent or predisposing conditions)
Blastic plasmacytoid dendritic cell neoplasms	Blastic plasmacytoid dendritic cell neoplasms (discussed in histiocytic dendritic cell neoplasms)
Acute leukemia of ambiguous lineage	Acute leukemias of mixed or ambiguous lineage (discussed in myeloid proliferations and neoplasms)
B-lymphoblastic leukemia/lymphoma	B-lymphoblastic leukemia/lymphoma (discussed in B-cell lymphoid proliferations and lymphomas)
T-lymphoblastic leukemia/lymphoma	T-lymphoblastic leukemia/lymphoma (discussed in T-cell and NK-cell lymphoid proliferations and lymphomas)

Abbreviations: ICC, International Consensus Classification; JMML, juvenile myelomonocytic leukemia; MDS, myelodysplastic syndrome; NK, natural killer.

AML

Both ICC and WHO-5 have made significant changes to the classification with the intent to prioritize genetics in defining specific subtypes. Both classifications expand the category of genetically defined entities to include uncommon but AML defining cytogenetic abnormalities such as AML with t(7;12) (q36.3;p13.2)/*MNX1::ETV6* rearrangements. In the presence of these abnormalities, a diagnosis of AML can be made with a blast count of <20%. Similarly, both classifications emphasize the use of genetics rather than morphology in defining myelodysplasia-related AML. In addition to chromosomal abnormalities, both classifications have expanded to include gene mutations *in ASXL1*, *BCOR*, *EZH2*, *SF3B1*, *SRSF2*, *STAG2*, *U2AF1*, or *ZRSR2* to allow for a diagnosis of AML-MR. The ICC, but not WHO-5, also includes *RUNX1* in the group of genes that can be used to define AML with myelodysplasia-related gene mutations. In addition, the ICC mirrors the ELN2022 recommendations to generate a hierarchical classification of AML.[4] In this scheme, the presence of mutated TP53 at a VAF ≥10% would result in a diagnosis of MDS/AML (blasts ≥10%) or AML (blasts ≥20%) with mutated *TP53*. In WHO-5, such disease could be variably classified as MD-IB2, erythroleukemia, MN, secondary, etc depending on the morphology and antecedent history. The two schemes also diverge in their approach to classification of AML without defining genetic abnormalities. WHO-5 formally retains a category of AML, defined by differentiation. In contrast, the ICC uses the broad category of AML not otherwise specified (AML, NOS) with the caveat that the pathologist may continue to subclassify such cases on the basis of morphology and cytochemistry if desired. Finally, although WHO-5 retains the category of MNs, secondary to include MNs after cytotoxic therapy and MNs associated with germline predisposition, the ICC recommends the use of diagnostic qualifiers therapy-related, progressing from MDS, progressing from MDS/MPN and germline predisposition to acknowledge antecedent history and genetic background. Therefore, although much has been made for the elimination of the category of therapy-related MNs by ICC, the use of appropriate classifiers will result in comparable diagnoses if the recommendations of the two classifications are carefully followed.

UPDATING MDS PROGNOSIS IN THE MOLECULAR ERA

Early Prognostic Tools

Initially recognized as a distinct malignant disease by the 1982 French-American-British group,[16] MDSs now comprise the most common clonal myeloid disorder in the

TABLE 3. ICC and WHO-5 Classification of MDS

ICC	WHO-5
Precursor lesions Clonal cytopenia of undetermined significance	Myeloid precursor lesions Clonal cytopenia of undetermined significance
MDS with mutated SF3B1 (MDS-SF3B1) MDS with del(5q) MDS with mutated TP53	MDS with defining genetic abnormalities MDS with low blasts and SF3B1 mutation (MDS-SF3B1) MDS with low blasts and 5q deletion (MDS-5q) MDS with biallelic TP53 inactivation (MDS-biTP53)
MDS, NOS with single lineage dysplasia MDS, NOS with multilineage dysplasia	MDS, morphologically defined MDS with low blasts (MDS-LB) Subtype MDS-LB-SLD Subtype MDS-LB-MLD MDS, hypoplastic
MDS with excess blasts (MDS-EB) MDS/AML or MDS/AML with mutated *TP53*	MDS with increased blasts (MDS-IB) MDS with increased blasts-1 (MDS-IB1) MDS with increased blasts-2 (MDS-IB2) MDS with fibrosis (MDS-F)

Abbreviations: ICC, International Consensus Classification; MDS, myelodysplastic syndrome; MLD, multilineage dysplasia; NOS, not otherwise specified; SLD, single-lineage dysplasia.

world. MDS varies in natural history from mild isolated cytopenia to bone marrow failure and high risk of evolution to AML.[17] Given this range of clinical outcomes, management also varies widely: some patients may be able to undergo surveillance with peripheral blood tests for years without any therapeutic intervention while others may need aggressive monitoring, dense transfusion support, chemotherapy, and hematopoietic stem-cell transplantation (HSCT) for curative intent.

Efforts to assess disease risk and predict outcomes have evolved over time. The initial prognostication tool published in 1997 was the International Prognostic Scoring System (IPSS),[18] which incorporated bone marrow blast percentage, cytogenetic risk category, and number of cytopenias. Patients were grouped into low, intermediate-1, intermediate-2, and high-risk groups by IPSS. In 2007, the WHO classification-based Prognostic Scoring System (WPSS)[19] was published using WHO subgroups, karyotype, and transfusion requirement to stratify patients among five risk categories. Subsequently the revised IPSS (IPSS-R)[20] was published in 2012; it refined multiple features including the degree of bone marrow blast percentage, additional cytogenetic risk groupings, and increased granularity for degree of cytopenias. The number of risk categories was further divided from 4 to 5 (very low, low, intermediate, high, and very high risks). These tools, and others,[19,21-23] have been incredibly useful over time to prognosticate for patients with MDS. However, an often-cited limitation was their inability to capture all relevant disease biology in a patient, as cytogenetics is the only genetic parameter included through the early 2020s. Furthermore, their applicability in treatment-related disease is also less clear.[21]

Integration of Molecular Genetics Into MDS Diagnosis and Classification

As NGS technologies have evolved, our understanding of molecular alterations has allowed us to better appreciate their impact on disease phenotype and natural history. For example, MDS with ring sideroblasts per the 2016 WHO MN classification was defined by at least 15% ring sideroblasts of nucleated erythroid cells or at least 5% in the presence of an *SF3B1* mutation.[24] On the basis of the fact that *SF3B1* mutation is highly associated with this clinicopathologic entity,[25] classification schemas reclassified this entity in 2022 on the basis of the presence of this mutation as opposed to morphologic features.[6,7] Further complexity underlies the pathologic effect of gene mutations as different amino acid substitutions can have varying prognostic effects[26] as can variant allele frequencies. The *TP53* mutations are an excellent example of the latter[27] and have long been a harbinger of inferior outcomes. Multihit *TP53* mutations identifies aggressive disease regardless of blast count, therapy relatedness,[28,29] or IPSS-R.[14] Per the 2022 ICC, MDS/AML with *TP53* mutation is recognized as a composite disease group with 10%-19% blasts[6] given that outcomes do not appear to be affected by blast count or therapy relatedness in the presence of this dismal prognostic feature.[28]

Integration of Molecular Data Into Prognostic Schemas

Given the increasing availability and implications of molecular data in MDS, multiple molecular genetic prognostic tools have been recently published. First, the EuroMDS consortium studied a population of more than 2,000 patients with MDS to first develop a prognostic tool that

incorporated 63 clinical and genomic variables, including mutations affecting 47 genes.[30] Eight groups were identified: patients with *SF3B1* mutations, *TP53* mutations and/or complex karyotype, *SRSF2* mutations, *U2AF1* mutations associated with the deletion of chromosome 20q and/or abnormalities of chromosome 7, AML-like mutation patterns, and finally, those without specific genomic profiles. The SF3B1 and SRSF2 groups were further divided into additional groups based on comutation patterns. This model was independently validated in a cohort of 318 patients and was shown to improve prognostic assessment beyond conventional age-adjusted IPSS-R.

Next, a multicenter group built the personalized prediction model for myelodysplastic syndromes using artificial intelligence software and a cohort of nearly 1,500 patients with MDS from Europe and the United States.[31] Aside from the clinical variables included in the IPSS-R, this model included the absolute lymphocyte and monocyte counts, peripheral white blood cell count, peripheral blast percentage, patient age, and WHO 2016 subtype. Relevant molecular data included the number of mutations and presence of mutations in seven genes: *SF3B1*, *STAG2*, *RUNX1*, *RAD21*, *SRSF2*, *ASXL1*, and *TP53*. This model groups patients in the same risk strata as the IPSS-R. Again, this model was found to outperform prognostication from IPSS and IPSS-R.

The next iteration of a molecularly based prognostic schema published was the IPSS-Molecular (IPSS-M)[32] which was developed using a cohort of almost 3,000 patients with MDS. Multihit *TP53* state, *FLT3* mutations, and partial tandem deletion of the MLL gene were adverse predictors, whereas SF3B1 associated with favorable outcomes. The model, available online (https://mds-risk-model.com/), uses clinical factors, cytogenetics, and molecular features to categorize MDS across six groups (very low, low, moderate low, moderate high, high, and very high). Sixteen genes with significant prognostic value were included, as were the presence of up to 2 of 15 residual genes. Like the above models, IPSS-M improves risk stratification as compared with IPSS-R, but uniquely it offers flexibility (given the ability to note input values are missing) and a high degree of personalization (as the output value is on a continuous scale essentially unique to that person).

Finally, the GenoMed4All consortium published two stratification tools incorporating sex, one of which also incorporates molecular features.[33] This group used four different MDS cohorts with a total of more than 13,000 patients to evaluate for a prognostic effect of sex on outcomes in MDS. Specific genes and mutation pathways were more specific to women (*TP53*, *DNMT3A*) and others to men (*ASXL1*, *SRSF2*, *ZRSR2*, *DDX41*, *IDH2*, *TET2*, and *U2AF1*). In all cohorts studied, men had worse median overall survival than women. Both tools are available online (https://mds.itb.cnr.it/#/mds/home): The sex-informed prognostic scoring system uses the same variables as the IPSS-R plus age and sex, whereas the sex-informed genomic scoring system also incorporates 12 cytogenetic and 22 molecular aberrations. Both systems have the same five risk categories as IPSS-R, and about half of patients were restratified by this sex- and genomic-informed approach depending on the cohort.

The Future of MN Risk Assessment

Although currently there is no formal consensus around which of the above risk schemas to use routinely, the guidelines[34] all favor universal incorporation of molecular data for clinical care and ongoing assessment for clinical trial eligibility and risk stratification. The different schemas vary in the data they require, risk categories, and availability of online platforms, but ongoing interest and consensus are building. One further complicating issue remains the notion that there is less clear value in using a blast percentage cutoff to distinguish MDS and AML, given the increasing evidence that disease genetics drives phenotype,[15,35] including blast count. If MDS and AML are to be considered the same disease in certain blast percent ranges[6] and disease genetics are the ultimate harbinger of outcome, the future may require a unifying tool to stratify risk among the spectrum of MNs. As MDS and AML continue to be studied, we will increasingly appreciate the relationship between disease genetics, phenotype, and risk. Finally, now that CCUS is a pathologic/genetic disease entity, there is the need to prognosticate for these patients as to who is more likely to evolve to overt myeloid disease requiring therapeutic intervention. Future scoring systems to delineate this risk will be welcome in the clinic.[36]

INHERITED PREDISPOSITION TO HEMATOLOGIC MALIGNANCY SYNDROMES: RECOGNITION AND IMPLICATIONS FOR THE PRACTICING CLINICIAN

A growing subset of patients with cancer are now recognized to carry a germline genetic predisposition to malignancy. Before the availability of clinical genetic testing, recognition of genetic predisposition to malignancy relied on syndromic clinical features or concerning family history. The clinical phenotypes of these genetic conditions are highly variable, and patients with genetic predisposition to malignancy often lack apparent syndromic features.[37] Some genetic predisposition conditions, such as *CEBPA* or *DDX41* or *TP53*/Li Fraumeni, only manifest with cancer without associated syndromic features. The diagnosis of genetic predisposition to malignancy informs treatment decisions and clinical monitoring. Because of limitations of space, we will focus on germline genetic predisposition to myeloid malignancy, but many of these concepts are broadly relevant for genetic predisposition to malignancies more broadly.

Classification of Germline Genetic Predisposition to Myeloid Malignancy

Genetic predisposition to myeloid malignancy was recognized as a distinct category in both the 5th edition of the World Health Organization Classification of Hematolymphoid Tumors[7] and the 2022 International Consensus Classification of Lymphoid and Myeloid Neoplasms.[6] Both classifications include categories for hematologic neoplasms with germline predisposition: (1) without other organ dysfunction, (2) with a constitutional/preexisting platelet disorder, and (3) with potential organ dysfunction or affecting multiple organ systems, which includes bone marrow failure syndromes, RASopathies, and Down syndrome. Additional or provisional conditions are also discussed. Appending a qualifier to the diagnosis of MDS or AML (MN with germline pathogenic variants in [gene]) allows a scalable diagnostic approach that can adjust as new genes are identified in this rapidly growing field.

Clinical Implications of Germline Genetic Predisposition to Myeloid Malignancy

Diagnosis of genetic predisposition to myeloid malignancy informs clinical care. Many genetic predisposition conditions require tailored therapy to avoid excessive treatment-related toxicities. For example, patients with Fanconi anemia, a condition caused by mutations in genes functioning in DNA repair, are sensitive to genotoxic agents and required individualized therapy for their malignancies.[38] Some genetic predisposition conditions are associated with comorbidities that increase risks of treatment-related morbidities. Patients with telomere biology disorders (TBDs), also known as dyskeratosis congenita, are prone to develop pulmonary fibrosis, liver disease, and arteriovenous malformations.[39] Patients with TBD benefit from evaluation for such complications to guide treatment choice, and clinical trials for specific transplant regimens for these patients are underway. Patients with germline *GATA2* mutations are at risk for severe infectious complications because of immune dysfunction, so some patients may benefit from early HSCT.[40] Some genetic predisposition conditions are associated with both hematologic and solid tumors, so diagnosis allows initiation of appropriate surveillance, particularly since the risk of secondary malignancies may be elevated after chemotherapy or radiation. For some of these genetic predisposition conditions, such as inherited bone marrow failure syndromes, HSCT is the curative treatment of choice for myeloid malignancies. Patients with genetic predisposition conditions may also be prone to emergence of additional leukemic clones unless treated with a HSCT. Diagnosis of a genetic predisposition condition allows testing of potential HLA-matched family donors to avoid choosing an affected, but clinically unrecognized, donor. For young families, early diagnosis provides opportunities for family planning.

Recognition of genetic predisposition to myeloid malignancy also guides diagnosis of hematologic malignancies. Many of these conditions are characterized by a high level of baseline dysplasias that may be mistaken for malignancy.[41] For example, patients with germline variants in *RUNX1* or *GATA2* may have megakaryocyte dysplasia without malignancy. Early diagnosis before the development of malignancy allows a baseline marrow examination for comparative evaluation of increasing dysplasia. For patients with genetic bone marrow failure syndromes, the observation of progressive cytopenias with increasing marrow cellularity warrants further evaluation for potential clonal evolution. Many of these genetic predisposition conditions are associated with bone marrow failure, which further complicates the diagnosis of myeloid malignancy. The clinical evaluation of clonal abnormalities may also be affected by an underlying germline predisposition condition. For example, clonal deletions of 20q are frequently observed in patients with Shwachman Diamond syndrome but are not associated with increased risk of clonal evolution.[42] Indeed, such clones result in adaptive somatic reversion of the germline genetic abnormality.[43,44]

Caution is needed in clinical decision making on the basis of germline variants. The identification of a heterozygous mutation in a gene associated with a recessive cancer predisposition syndrome often elicits consternation. An example is the frequent observation of heterozygous mutations in genes causing Fanconi anemia, a DNA repair disorder, in patients with myeloid malignancy. No increased cancer risk was identified in a study including older relatives of patients with Fanconi anemia, with the exception of the known dominant solid tumor predisposition genes *BRCA1*, *BRCA2*, *PALB2*, *BRIP1*, and *RAD51C*.[45] However, orthogonal testing for chromosomal breakage may be helpful to assess for potential pathogenic variants on the second allele. For HSCT using related donors, potential clinical implications of donor mutations in genes predisposing to nonhematologic malignancies remain to be clarified.

Whom to Screen for Germline Genetic Predisposition to Myeloid Malignancy

In the past, recognition of a germline genetic predisposition condition relied primarily on clinical findings and family history; however, multiple studies have consistently demonstrated that a significant subset of patients are diagnosed by genetic testing without any other clinical suspicion for a predisposition condition. Although presentation with a myeloid malignancy in childhood or early adulthood is a flag for a potential germline genetic condition, patients with germline genetic predisposition may present with malignancy at any age.[46] Indeed,

patients with germline mutations in *DDX41* present with malignancies at older ages.[44] Patients with telomere biology disorders also often first present at older ages.[45]

A detailed clinical history and examination may identify clues to an underlying genetic predisposition condition. A preceding history of unexplained cytopenias or bone marrow failure raises suspicion for a genetic predisposition condition. Many, but not all, genetic predisposition conditions may have associated clinical findings such as congenital anomalies, short stature/poor growth, recurrent infections, or a history of excessive sensitivity to genotoxic treatments. Patients with telomere biology disorders may develop liver disease or pulmonary fibrosis. Some findings are nonspecific such as a history of eczema (germline *RUNX1*, Shwachman Diamond syndrome), warts or lymphedema (*GATA2* syndrome), easy bleeding (*RUNX1*, *ANKRD26*, *ETV6*), or skin hyper/hypopigmention (Fanconi anemia, TBD) but warrant attention in patients presenting with myeloid malignancy. A personal or family history of malignancy is also a red flag, especially a history of more than one malignancy in a given individual, an unusually young age at malignancy diagnosis, multiple family members with malignancy, or excessive sensitivity to genotoxic therapies. A related donor with a cytopenia(s), abnormal marrow examination, or poor stem-cell mobilization also warrants further evaluation for a germline genetic predisposition.

Laboratory testing is guided by clinical findings. A preceding history of unexplained macrocytosis may flag a genetic predisposition to myeloid malignancy. Chromosomal breakage testing for Fanconi anemia is recommended for pediatric and young adult patients with bone marrow failure or MDS or adults with a concerning history/physical examination or myeloid malignancy and a history of squamous cell carcinoma of the head, neck, GI tract, or vulva. Telomere length testing is also helpful to diagnose patients with TBD. Caution is needed to interpret telomere length in adults and should be integrated with genetic testing. Of note, chromosomal breakage or telomere length testing are difficult to assess in patients with peripheral blasts or recent genotoxic therapy. Screening for immunologic abnormalities, including immunoglobulin levels and lymphocyte subsets (T cells, B cells, and natural killer cells), can be helpful to flag germline conditions associated with immune deficiencies and is best sent before initiation of therapy.

Some gene mutations may be of either somatic or germline origin, so identification of a variant in such a gene in a somatic cancer genetic panel needs further assessment. Persistence of a mutation at a high VAF in remission may flag a germline origin. The gold standard to establish a germline variant is to test a nonhematopoietic tissue such as fibroblasts from a skin biopsy. DNA from saliva, hair follicles, and nails may contain blood cells and are not currently recommended to differentiate somatic versus germline mutations for hematologic malignancies. Somatic genetic panels are not interchangeable with germline genetic panels because of differences in genes included, regions sequenced within a given gene, differences in analytic pipelines for somatic versus germline variant curation, limitations in analysis of copy number variants/gene deletions, and confounding effects of somatic reversions.

Since the risk of a genetic predisposition condition is high in pediatric and young adult patients with myeloid malignancy, genetic evaluation is increasingly integrated into the diagnostic workup. Clinical practice is evolving for adults with myeloid malignancy as studies continue to emerge demonstrating genetic predisposition in increasing numbers of older patients. The field is rapidly advancing, so consultation is recommended with centers experienced in the diagnosis and clinical care of patients with genetic predisposition to myeloid malignancy.

In conclusion, genetic mutational profiling is increasing our understanding of the biology of myeloid malignancies—both through somatic and germline genetics. This added knowledge is now used for possibly earlier diagnosis, more precise disease classification and risk stratification, and in some instances, to guide therapeutic decision making in a biologically rational way. The next frontiers include unification of classification schema, access to a broader array of therapeutics, and personalized treatment options for all lower- and higher-risk myeloid malignancies.

Embracing Myeloma Chimeric Antigen Receptor-T: From Scientific Design to Clinical Impact

Hitomi Hosoya, MD[1]; Paula Rodriguez-Otero, MD[2]; Surbhi Sidana, MD[1]; and Ivan M. Borrello, MD[3]

Overview

Despite recent advancement of treatment strategies in multiple myeloma (MM), patients with relapsed/refractory MM disease, particularly after triple-class refractoriness, continue to have poor prognosis. Chimeric antigen receptor (CAR-T) cells were developed and applied to improve outcomes in this setting, and two products, idecabtagene vicleucel and ciltacabtagene autoleucel, both targeting B-cell maturation antigen, have been approved by the Food and Drug Administration in the United States and European Medicines Agency in Europe. Both have shown unprecedented clinical outcomes with high response rate and prolonged progression-free survival and overall survival in this patient population with grim prognosis. Currently, further investigations are ongoing for CAR-T targeting different tumor antigens such as G protein–coupled receptor, class C, group 5, member D or with different combinations of intracellular signaling domains, as well as fourth-generation CAR-T with antigen-unrestricted inducible cytokines. Although CAR-T therapies hold hopes and enthusiasm from the myeloma community, several hurdles remain before these treatments become available for all patients in need. These barriers include CAR-T-cell manufacturing availability, access to administering centers, financial cost, caregivers' availability, and socioeconomic and racial disparities. Expanding clinical trial eligibility criteria and real-world data collection and analysis is crucial to understand the efficacy and safety of CAR-T in the patient cohort who tends to be excluded from current trials.

INTRODUCTION

The treatment landscape of patients with multiple myeloma (MM) has significantly evolved in recent years, leading to unprecedented survival rates.[1] Nevertheless, MM remains an incurable disease and patients continue to relapse requiring further therapy. Importantly, patients who have been previously exposed to the three main classes of agents, namely, proteasome inhibitors, immunomodulatory derivatives (IMIDs), and anti-CD38 monoclonal antibodies, have limited treatment options and poor survival.[2] In this setting of unmet medical need, novel T-cell–redirecting agents, with high clinical efficacy, have been developed, including chimeric antigen receptor (CAR-T) cell therapies and bispecific antibodies targeting not only the B-cell maturation antigen (BCMA) but also G protein-coupled receptor, class C, group 5, member D (GPRC5D) or Fc receptor homolog 5, among others.[3-7]

Here, we discuss the design and biologic principles of CAR-T therapy for MM, clinical data, and barriers to access to CAR-T therapy.

THE DESIGN AND BIOLOGIC PRINCIPLES OF CAR-T CELLS FOR MM

First proposed by Eshhar et al,[8] CARs enable T cells to recognize and kill their targets expressing the cognate antigen through engagement of an antibody-derived single-chain variable fragment independent of major histocompatibility complex (MHC) restriction. CARs have evolved over the years: first-generation CARs only provided a T-cell receptor activating signals through expression of CD3ζ. Second-generation CARs added the intracellular domain of the costimulatory molecule, CD28, to deliver both activating signals and costimulatory signals as to enhance T-cell efficacy and persistence,[9] whereas the third generation modified the intracellular signaling domains with various costimulatory molecules from 4-1BB, CD28, or OX-40 to enhance performance.[10-12] These modifications in each generation of CAR-T cells have significantly improved the overall efficacy, and two products have obtained a Food and Drug Administration (FDA) approval to treat relapsed/refractory MM. However, despite the initial success, several challenges remain to enhance the therapeutic efficacy of this approach (Fig 1).

Identification of Suitable Myeloma Targets

BCMA is a receptor protein expressed on all healthy and malignant plasma cells and is a receptor for APRIL ligands, which regulate the development of B-cell immunity by supporting antibody production, immunoglobulin class switching, and plasma cell

PRACTICAL APPLICATIONS

- Patients with triple-class exposed (TCE) relapsed/refractory multiple myeloma have an unmet medical need with poor outcomes when treated with standard-of-care regimens. In this setting, B-cell maturation antigen (BCMA)–directed agents and, in particular, BCMA-directed chimeric antigen receptor (CAR-T) cells have demonstrated encouraging clinical efficacy, leading to the approval of two CAR-T-cell constructs (idecabtagene-vicleucel [ide-cel] and ciltacabtagene-autoleucel [cilta-cel]).
- ide-cel and cilta-cel have also been evaluated in early disease settings in the population of unmet clinical need. Indeed, evidence from two different phase 3 randomized trials has demonstrated that treatment with BCMA-CAR-T-cell therapies is superior to standard-of-care regimens in the setting of patients with TCE early relapse disease (KarMMa-3 trial—ide-cel) and in patients with early relapse and lenalidomide-refractory disease.

homeostasis and proliferation.[13,14] It has a favorable therapeutic index as its selective expression is limited to late-stage B cells, short-lived proliferating plasmablasts, and long-lived plasma cells. Importantly, expression is increased on malignant compared with healthy plasma cells.[15] Interestingly, expression of BCMA wanes over time because of enzymatic cleavage of the protein via gamma-secretase cleavage of the extracellular domain. Lower antigen expression caused by either shedding or downregulation has been reported as one mechanism of relapse in BCMA and other CAR-T-cell therapies.[16,17] To this effect, gamma secretase inhibitors[18] alone or in combination with all trans-retinoic acid[19] are being used to increase BCMA surface antigen expression and improve therapeutic efficacy of CAR-T-cell therapy.[20] In fact, KarMMa-7 is currently exploring several adjunctive agents to enhance the overall efficacy of BCMA CAR-T including a novel gamma-secretase inhibitor. An alternative approach to maximize efficacy has been to generate CARs to additional targets.

GPRC5D is another intriguing target; its expression is limited to malignant plasma cells as well as keratinocyte-derived tissues such as nail, skin, and hair follicles. One study observed that its expression levels correlated with a shorter progression-free survival (PFS).[21] Early clinical trials show evidence of promising clinical activity even in patients previously treated with BCMA therapies.[3,22]

CD38 has proven to be an excellent target of monoclonal antibodies and is also being examined in CAR-T cells.[23] Its targeting with monoclonal antibodies has dramatically changed the treatment paradigms in myeloma. However, in contrast to the abovementioned targets, CD38 expression is not only limited to plasma cells but also found on B cells, activated T cells, and erythrocytes.

There are also other targets being explored. CD229 is a SLAM receptor present on the surface of MM plasma cells in chemoresistant myeloma and is relatively absent on normal plasma cells.[24] In contrast to BCMA whose expression is mostly limited to the terminally differentiated plasma cells, CD229 is also found on transitional and memory B cells.[25,26] CD19 is also being explored on the basis of data, suggesting that the postgerminal memory B cell is, in fact, the clonogenic malignant precursor. As such, targeting this stem cell could potentially more effectively eradicate the disease, and this is being investigated in the clinical setting.[27-30]

Intracellular Signaling Domains

The intracellular signaling domains ultimately determine the efficacy and persistence of CAR-T cells. Although several costimulatory molecules exist such as CD28, 4-1BB, ICOS, and OX40, CD28 and 4-1BB are the two that have primarily been used. CD28-CD3ζ generates tonic signaling and increased

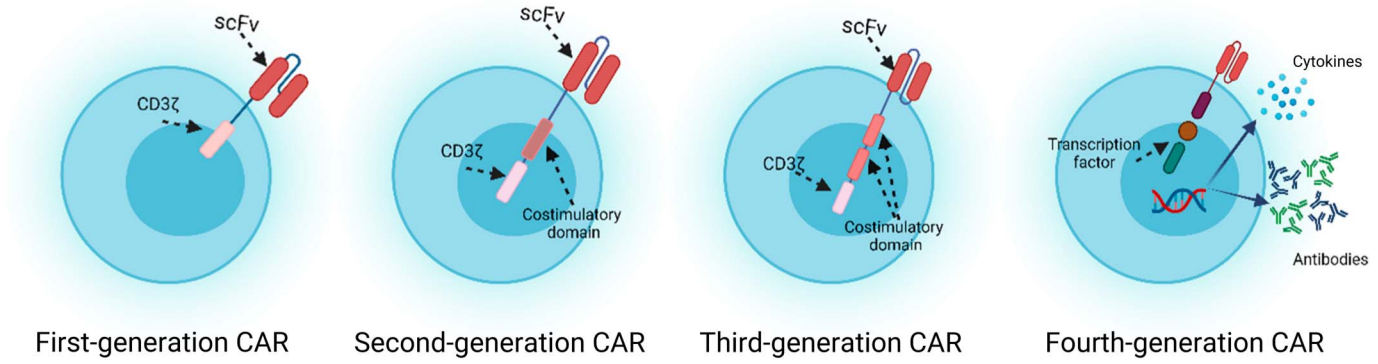

FIG 1. Main characteristics of different CAR-T generations (made with BioRender.com). CAR, chimeric antigen receptor; scFv, single-chain variable fragment.

NFkB activation, resulting in high cytotoxic efficacy and significant T-cell expansion but limited persistence, and likely generates a more severe cytokine release syndrome (CRS).[31,32] By contrast, 4-1BB skews toward greater effector memory (T_{EM}) and stem-cell memory (T_{SCM}) T cells, which translate into enhanced persistence and less exhaustion. Mechanistically, 4-1BB activates mammalian target of rapamycin and upregulates the antiapoptotic genes, Bcl-xL and BFL-1,[33] with a metabolic profile favoring fatty acid oxidation and mitochondrial biogenesis.[34] By contrast, CD28 leads to greater glycolysis and a more exhausted phenotype.[35] In summary, CD28 CAR-T cells show greater cytotoxicity but less persistence, whereas 4-1BB results in less cytotoxicity but greater persistence.

Third-generation CARs attempted to titrate the activation of CD28 with persistence of 4-1BB. Preclinical data demonstrated that combined stimulation with both CD28 and 4-1BB generated more efficient CAR-T cells. It increased cytotoxicity and the production of interferon-gamma, tumor necrosis factor-alpha, and granulocyte-macrophage colony stimulating factor, upregulated the antiapoptotic protein, Bcl-X_L, and prolonged the activation of the phosphoinositide 3-kinase/serine/threonine specific protein kinases pathway.[11] Additional preclinical studies showed that combining 4-1BB with a modified CD28 domain resulted in better killing, antigen recognition at lower densities, greater polyfunctional cytokine production, and greater persistence.[36]

A more recent advance has been the development of: T cells redirected for antigen-unrestricted cytokine-initiated killing (TRUCKs) also considered the fourth generation of CAR-T cells. This concept was initially developed as a strategy to overcome the profound immunosuppressive environment of solid tumors but has potential applicability even for hematologic malignancies.[37] The TRUCKs are equipped with tumor-specific CARs and a nuclear factor of activated T cells-inducible expression cassette coding for a transgenic protein, typically a cytokine. After TRUCKs bind to the antigen, CAR signaling induces NFAT phosphorylation, which eventually drives transgene expression. The inducible cytokines that have been coengineered into CAR-T cells include IL-12, IL-15, and IL-18.[38] In preclinical models, TRUCKs have shown superior antitumor efficacy compared with early-generation CARs coadministered with the exogenous cytokine. This approach allows for high local expression of the cytokine to maximize antitumor efficacy and minimize toxicity.

T-Cell Activation and Exhaustion

As the limitations of CAR-T cells become more apparent, increasing interest exists in understanding the determinants of long-term disease control. In addition to biologic attributes that can be conferred by the CAR construct itself, the overall health of T cells plays a critical role in mediating both cytotoxicity and persistence. Chronic antigen exposure that defines a cancer-bearing host has been shown to induce a state of T-cell exhaustion characterized by reduced effector function, limited cytokine secretion, and increased expression of inhibitory receptors to generate exhausted T cells known as Tex.[39] However, Tex contain subsets of proliferation-competent precursors and also a less proliferative, terminally differentiated effector T cell. Wherry et al recently mapped out a hierarchical model using acute and chronic infection of lymphocytic choriomeningitis virus as a model and identified four subsets: (1) Tex^{prog1}—hypoproliferative, stem-cell–like progenitors located primarily in lymphoid tissues (Tcf-1^{+++}, PD-1^{low}, Ki67^{low}); (2) Tex^{prog2}—proliferative progenitors that transition from lymphoid tissue to blood (Tcf-1^{++}, PD-1^{low}, Ki67^{int}); (3) Tex^{int}—an intermediate effector subset found in blood (Tcf-1^{low}, PD-1^{int}, Ki67^{high}); and (4) Tex^{term}—a hypoproliferative, terminal effector population with low persistence absent in the blood and only found in blood accessible organs (Tcf-1^{-}, PD-1^{high}, Ki67^{low}).[40] These subsets are increasingly being recognized as critical to understand the quality and efficacy of the CAR-T-cell response (Fig 2).

A major barrier to clinical responses following CAR-T cells has been T-cell persistence. On infusion, CAR-T cells undergo rapid proliferation with associated methylation changes, resulting in repression of genes responsible for the memory phenotype and activation of a gene pattern consistent with a more exhausted phenotype.[41] Prevention of the transition to an exhausted phenotype is a major target of potential intervention to enhance persistence and possibly clinical outcomes. Evidence that the T-cell health dictates clinical outcomes has also been elegantly shown in patients with chronic lymphatic leukemia treated with CD19 CAR-T cells.[42-44] In analyzing the CAR-T products from responders and nonresponders, they reported that responders possessed a stem-cell memory, nonexhausted phenotype and exhibited decreased glycolytic metabolism. Interestingly, the responders also had higher expression of STAT3 and signaling mediators and targets including IL-6 and IL-17, suggesting a critical role of STAT3 activation in generating more potent, less differentiated T cells.

In summary, as CAR-T-cell therapies continue to demonstrate remarkable clinical efficacy, there is an increasing awareness of their limitations. To enhance the therapeutic benefit, research is focusing on new surface targets and cell persistence. Persistence is being addressed by modifications of the intracellular signaling domains beyond CD28 or 4-1BB and increasing our understanding of the importance of the overall biology of T-cell exhaustion and its metabolic state. A summary of the main mechanism of resistance and potential avenues for improvement is included in Table 1.

CLINICAL IMPACT AND SEQUENCING OF CAR-T THERAPY FOR MM

Currently, two different BCMA-directed CAR-T-cell products have been approved for the treatment of patients with

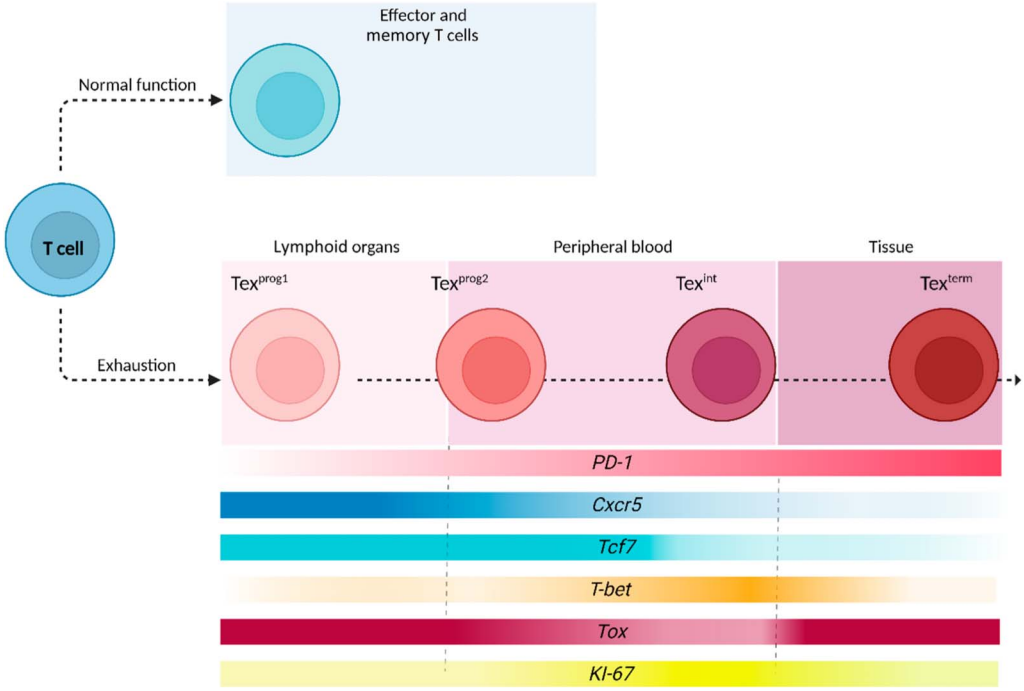

FIG 2. Schematic representation of progressive T-cell exhaustion characterized by reduced effector function, limited cytokine secretion, and increased expression of inhibitory signals in the setting of chronic antigen exposure.

triple-class exposed (TCE) relapsed/refractory MM (RRMM), a population with a high unmet clinical need.

Idecabtagene-vicleucel (ide-cel, bb2121, ABECMA) was the first cellular therapy approved for the treatment of TCE RRMM on the basis of the results of the phase 2 pivotal KarMMa trial.[45] Overall, 128 patients received a single ide-cel infusion. The population of patients was heavily pretreated, with a median number of six previous lines (range, 3-18), and 84% of them were triple-class refractory. The overall response rate (ORR) was 73% among all treated patients and 81% in those receiving a single infusion at the target dose level of 450 $\times$ 10^6 CAR-T+ cells with 33% and

TABLE 1. Potential Mechanism of Resistance to CAR-T-Cell Therapy and Potential Avenues for Improvement

Mechanism of Resistance	Potential Solution	Rationale
Heterogeneity in target expression in the tumor	Dual targeting (ie, BCMA-CD38, BCMA-CD19)	Will target tumor cells with low expression of BCMA
	Combinations with gamma-secretase inhibitors	Increase target density in the tumor cell
Loss of expression of BCMA because of antigen loss or mutations	Development of CAR-T targeting different antigens such as GPRC5d, among others	
Lack of expansion	Increase memory T-cell phenotypes in the product	Incubation with PI3K inhibitors
	Higher CD4/CD8 ratio	
Loss of persistence	Reduce immunogenicity of CAR constructs	Humanized constructs
	Increase proportion of memory T-cell subsets	
Impaired functional persistence because of T-cell exhaustion	Combinations with immunomodulatory drugs such as IMIDs, checkpoint inhibitors, and anti-CD38 monoclonal antibodies, among others	
Impaired T-cell fitness in the apheresis product	Avoid previous therapies that may alter T-cell composition or decrease proportion of T cells	Avoid high-dose alkylators
		Possibility to prime T cells before apheresis to increase functionality
Immunosuppressive microenvironment	Third-generation CAR-T cells or TRUCKs	

Abbreviations: BCMA, B-cell maturation antigen; CAR, chimeric antigen receptor; GPRC5d, G protein–coupled receptor, class C, group 5, member D; IMIDs, immunomodulatory derivatives; PI3K, phosphoinositide 3-kinase; TRUCKs, T cells redirected for antigen-unrestricted cytokine-initiated killing.

39% of complete responses (CR), respectively. The median PFS was 8.8 months in the overall population and was longer in patients receiving the target dose (median PFS, 12.1 months). The median overall survival (OS) was 24.8 months (95% CI, 19.9 to 31.2). Safety was manageable with CRS reported in 84% of patients, with the majority of events being grade 1 or 2. Neurologic complications were less common, reported in 18% of patients and mostly grade 1-2. Cytopenias were frequent, not dose-related, with the median time to recovery from grade ≥3 neutropenia and thrombocytopenia of 2 and 3 months, respectively.[45] These data supported the approval of ide-cel use after the receipt of at least four previous lines of therapy in patients in the United States and after at least three previous therapies in patients in the European Union.[46]

Ciltacabtagene-autoleucel (former LCAR-B38M, cilta-cel, CARVIKTY) is another second-generation CAR-T cell containing two BCMA binding domains, which was approved on the basis of the results of the phase 2 CARTITUDE-1 study. Overall, 97 patients were infused with a median number of six previous lines and 87.6% were triple-class refractory. The ORR was 97.9%, with 82.5% of patients achieving a stringent CR (sCR). With a median follow-up of 27.7 months in the most recent update, median PFS has not yet been reached, with the 27-month PFS of 54.9% (95% CI, 44 to 64.6) and 64.2% (95% CI, 51.9 to 74.1) for patients in sCR. The 27 month OS was 70.4% (95% CI, 60.1 to 78.6). Regarding safety, cytopenias and CRS were the most frequent treatment-related adverse events reported. Any grade neutropenia was present in 96%, which is grade ≥3 in 95% of patients. The incidence of CRS was 95%, mostly grade 1-2 with a median time to onset of 7 days (range, 1-12). Neurologic events were reported in 20 patients. Among these, 16 of 20 presented immune effector cell–associated neurotoxicity syndrome (ICANS) and 12 patients presented with other neurotoxicities, of whom 5 showed a movement and neurocognitive disorder occurring with a median time to onset of 27.0 (IQR, 16.0-73.0) days.[47]

Albeit impressive clinical results are obtained thus far, no plateau is seen in the survival curves and relapses continue to occur. The current and subsequent evolution is focused on the development of new constructs and the early use in populations of unmet clinical need.

In this context, patients with early relapse disease that is TCE continue to have poor outcomes with no standard of care available. ide-cel has been evaluated in this setting in the phase 3 randomized KarMMa-3 trial. Patients with RRMM who had received two to four previous lines of therapy and were TCE were included. Enrolled patients were randomly assigned 2:1 to receive ide-cel or standard regimens.[48] Patients allocated in the ide-cel arm received a single infusion of ide-cel with a target dose range of 150 to 450 $\times 10^6$ CAR-T+ cells. Patients assigned to the standard regimen arm were treated with one of five regimens chosen by the investigator at the time of random assignment on the basis of exposure and refractoriness to previous therapies. Treatment in the standard arm continued until disease progression, unacceptable toxicity, or study withdrawal. The primary end point was PFS assessed by the independent review committee in the intention-to-treat (ITT) population, with ORR and OS as key secondary end points. Of the 386 patients randomly assigned, 254 were assigned to the ide-cel group (ITT) and 132 to the standard regimen arm (ITT); 225 patients received a single infusion of ide-cel (median dose of 445 $\times 10^6$ CAR+ T cells), whereas 126 received the standard treatment, with daratumumab-pomalidomide-dexamethasone being the regimen most frequently used. Baseline characteristics were balanced between the two treatment arms. The median number of previous regimens was 3, and overall, 65% of the patients were triple-class refractory with a median time of 4 years from diagnosis to study entry and a median time to progression on last previous antimyeloma therapy of only 7 months in the two arms. At a median follow-up of 18.6 months, PFS was significantly longer with ide-cel, with a median PFS of 13.3 months (95% CI, 11.8 to 16.1) versus 4.4 months (95% CI, 3.4 to 5.9) with standard regimens (hazard ratio, 0.49 [95% CI, 0.38 to 0.65]; P value $< .0001$). Notably, PFS benefit of ide-cel was observed across multiple patient subgroups including older age, high-risk cytogenetic abnormalities, high tumor burden, or extramedullary disease. The PFS benefit was also seen in patients regardless of the number of previous lines and in patients with triple-class refractory disease. Treatment with ide-cel also resulted in a higher ORR (71% *v* 42%; odds ratio, 3.47 [95% CI, 2.24 to 5.39]; P value $< .0001$). OS data were immature and remain blinded. Regarding safety, the most common adverse events were hematologic. Grade 5 adverse events occurred in 36 patients in the ide-cel arm and eight in the standard regimen arm. Importantly, 18 of 36 and three of eight had grade 5 events consistent with disease progression. Overall, the safety profile of ide-cel was consistent with previous studies with no new safety signals.[48]

In the same direction, patients with early relapse disease and disease refractory to lenalidomide also represent a population with poor outcomes with current approved therapies. Previous preliminary data with cilta-cel in cohort A of the phase 2 CARTITUDE-2 trial demonstrated encouraging efficacy with an ORR of 95%, a CR rate of 85%, and a 12-month PFS rate of 84% (95% CI, 59.1 to 94.7).[49] The randomized phase 3 CARTITUDE-4 trial compares cilta-cel with standard-of-care (SOC) therapy in lenalidomide-refractory patients with 1-3 previous lines of therapy. The two control SOC regimens used were pomalidomide, bortezomib, and dexamethasone or daratumumab, pomalidomide,

and dexamethasone. cilta-cel has demonstrated a significant improvement in PFS in the first prespecified interim analysis. The full disclosure of the data is still pending.[50]

Furthermore, both cilta-cel and ide-cel have been evaluated in other settings of unmet clinical need and functional high risk such as patients with early relapse after frontline therapy. In cohort B of the CARTITUDE-2 trial, 19 patients with early relapse (within first 12 months) after frontline therapy were treated. The ORR was 100%, and 89% of patients achieved at least CR, with an 18-month PFS rate of 83% (95% CI, 55.9 to 94.3).[51] Safety profile was comparable with previous publications without any new safety signals.[49,51] Similarly, ide-cel was evaluated 37 patients with early relapse, here defined as progressive disease within 18 months after diagnosis. 86% were refractory to any IMID. At a median follow-up of 21.5 months, the ORR was 83.8% and the CR rate was 45.9%. The median PFS was 11.4 months (95% CI, 5.6 to 19.6), and the 24-month OS rate was 84.7%. Safety was consistent with previous reports.[52] ide-cel was also tested in patients with suboptimal response after frontline autologous stem-cell transplantation, a patient population with short PFS and poor prognosis. A total of 31 patients received a single CAR-T infusion with a median dose of 440 $\times$ 10^6 CAR T+ cells (range, 244.9-514.5). The ORR was 87.1%, and the CR rate was 74.2%. Median PFS has not yet been reached with a PFS rate at 24 months of 83.1%. Interestingly, the safety profile was comparable with previous reports with the exception of one grade 3 Parkinsonism event reported in one patient at day 22 post–ide-cel infusion.[53] Other studies are ongoing evaluating these two constructs in other populations including the frontline setting (BMTCTN1902—ClinicalTrials.gov identifier: NCT05032820, CARTITUDE-5—ClinicalTrials.gov identifier: NCT04923893, and CARTITUDE-6—ClinicalTrials.gov identifier: NCT04181827; Table 2).

Altogether these results have established BCMA-CAR-T-cell therapy as a new standard of care for the treatment of TCE RRMM in either late or early RRMM. In addition, other BCMA-targeted therapies (Table 3) are approved and available, such as bispecific antibodies (ie, teclistamab) or antibody drug conjugates (ADCs; ie, belantamab mafodotin—only in Europe). Therefore, understanding the correct sequence between the different BCMA-directed therapies is of utmost importance although the evidence is still rather scanty. In the real-world experience from the US Myeloma CAR-T consortium with ide-cel, the use of a previous BCMA-therapy negatively affected PFS with a median PFS of only 3.2 months (95% CI, 2.8 to not reported [NR]) versus 9.0 months (95% CI, 7.6 to NR) in BCMA-naïve patients.[60] Similarly, with cilta-cel, both ORR (60%) and PFS (median, 9 months [95% CI, 1.5 to 13.2]) were shorter in patients previously exposed to BCMA-ADC or bispecific as compared with BCMA-naïve patients treated in the CARTITUDE-1.[61] On the contrary, salvage therapy with bispecific antibodies in patients progressing after BCMA-CAR-T seems to be rather efficacious with an ORR of 52.2% with teclistamab[62] or 62.7% with talquetamab,[63] which is comparable with that of the BCMA-naïve cohorts, suggesting that whenever possible, CAR-T-cell therapy should be prioritized to prevent continuous T-cell exhaustion or BCMA downmodulation after continuous exposure to BCMA ADC or bispecific antibodies.

Future development is ongoing, with novel constructs and different targets[3,22] being explored aiming to overcome some of the limitations of current CAR-T-cell therapies, and the possibilities are endless. A summary of some of these novel products that have clinical data is included in Table 4.

BROADENING ACCESS TO NOVEL MM THERAPEUTICS

Novel immunotherapies, including the two FDA-approved CAR-T-cell products, ide-cel and cilta-cel, have shown remarkable efficacy in patients with relapsed/refractory MM who have received multiple lines of therapy.[6,47] Although the unprecedented response rates have been met with enthusiasm and hope from patients and the myeloma community, several hurdles remain before these treatments are routinely and widely available for all patients.

Hurdles to CAR-T access in myeloma include the limited availability of CAR-T products because of manufacturing constraints[72,73] and the limited number of centers that offer CAR-T therapy, creating a challenge for patients who do not live in close proximity to such centers or may not otherwise have access. Additional barriers to CAR-T therapy include overcoming socioeconomic and racial disparities that have been shown to affect access to novel therapies, including significant financial and caregiver burden during the treatment.[74] In this section, we will discuss these barriers and potential solutions to broadening CAR-T access for patients with RRMM.

CAR-T-Cell Availability

Since becoming commercially available, both ide-cel and cilta-cel have limited manufacturing availability. This is due in part to the shortage of commercial-grade good manufacturing process viral vectors needed to make CAR-T cells. Most designated centers are provided one to two slots per month for each product, resulting in a long waiting list of patients who are in desperate need of these products. The treating physicians at these centers must decide which patients receive these slots, which can pose an ethical challenge.[75,76] Some centers select patients on the basis of availability of alternate treatment options, disease burden, and aggressiveness of relapse. At some centers, likelihood of favorable response may factor into this decision making, with CAR-T being offered to patients whose disease is refractory but with less aggressive biology and lower disease

TABLE 2. Summary of Ongoing Studies Evaluating CAR-T-Cell Therapy in Earlier Lines of Therapy or in Combinations With Standard-of-Care Treatment

Trial	Study Population	Study Design	CAR Name	scFv Origin	Phase	No.	Antigen	Cell Source	End Point	Dose	Status

Abbreviations: BCMA, B-cell maturation antigen; CAR, chimeric antigen receptor; CR, complete response; CRS, cytokine release syndrome; DL, dose limiting; ICANS, immune effector cell–associated neurotoxicity syndrome; Tox, toxicity; NE, not evaluable; NR, not reported; ORR, overall response rate; PFS, progression-free survival; RRMM, relapsed and refractory multiple myeloma; scFv, single-chain variable fragment; VGPR, very good partial response.

[a]Cerebellar toxicity in two patients.

burden. Other centers select patients simply by the order they were listed in the list. One study showed that only 15% of patients with RRMM who were listed for commercial CAR-T received the therapy by 6 months and 29% by 12 months. About a third of patients died while waiting for the CAR-T therapy.[77] Enhancing manufacturing capacity will require significant commitment and investment from pharmaceutical partners who manufacture these products. Some pharmaceutical companies that make standard-of-care CAR-T products for lymphoma indications have moved to in-house manufacturing of viral vectors to have secure and constant availability of viral vector for manufacturing. Such effort is sought in manufacturers of ide-cel and cilta-cel. Another potential consideration would be to restrict CAR-T clinical trials to areas of urgent clinical need only, while awaiting the ramp-up of the CAR-T supply for standard-of-care manufacturing. The supply will also improve as other CAR-T-cell products become available commercially.

Access to CAR-T Centers

CAR-T therapy can only be given at select specialized centers and requires centers in the United States to meet accreditation requirements from Foundation for the Accreditation of Cellular Therapy (FACT). This creates geographic barriers to access as CAR-T therapy is mostly limited to large academic medical centers with hematopoietic transplant experience. Currently, there are fewer than 250 FACT-accredited centers that can provide cellular therapies across the United States.[78] These facilities are unevenly located across the country, resulting in a challenge in access to most patients. Even in clinical trials of CAR-T treatment, it was shown that about a quarter of patients lived over 2 hours away.[79] To undergo CAR-T therapy, patients are required to stay close to the treating centers for up to 30 days after CAR-T-cell infusion, resulting in significant direct and indirect financial costs of relocating and time away from paid work for patients and their caregivers. Many centers require patients to have a caregiver for 30 days post–CAR-T, and this can be a hurdle for some patients. These issues cannot be solved without thinking at a national and international level. Geographically uneven distribution of medical resources affects not only access to cellular therapy but also oncologic care in general. Having a better distribution of FACT-accredited facilities would improve access to CAR-T-cell therapy. In addition, assistance with medical leave for patients and caregivers, transportation centers, and local lodging would broaden access to CAR-T therapy.

Financial Cost

CAR-T products currently approved for RRMM carry a list price of $419,500 in US dollars for ide-cel and $465,000 USD for cilta-cel in the United States, which does not include the cost of hospitalization or outpatient specialized care. In 2019, the Center for Medicare and Medicaid Services finalized the decision for Medicare to cover CAR-T-cell therapies under FDA-approved indications. However, patients who are uninsured or underinsured have significant hurdles in accessing CAR-T therapy. In addition, out-of-pocket expenses including the cost of transportation and local lodging, co-pay for visits and medications, and short-term loss of income for the patient and their caregiver can pose a significant challenge for patients. In a study of patients with non-Hodgkin's lymphoma undergoing CAR-T therapy, the mean financial burden during CAR-T-cell therapy per patient was estimated to be $5,368, with the greatest financial burden coming from the lodging and meals for the patient and their caregivers.[80] Many programs use grants and other funding to support local housing cost during the treatment; however, this is not always available. Lowering the out-of-pocket expenses and securing appropriate financial assistance is crucial to improve access.

Socioeconomic and Racial Disparities

Access to CAR-T-cell therapy is limited especially for minorities and those in a lower socioeconomic stratum. A study performed with Vizient Clinical Database showed that the African American (AA) population, despite representing nearly 20% of newly diagnosed myeloma cases, made up only 1% of patients who received CAR-T-cell treatment in clinical trials.[79] Hispanic patients were under-represented at 5.4%. CAR-T therapy is not the only entity where we see disparities in access to care. It was demonstrated that utilization of bortezomib was 37% lower among AA patients compared with White patients,[81] and they were 37% less likely than White patients to undergo stem-cell transplantation even after adjusting for income and insurance.[81] This suggests that structural barriers may exist in the health care system, such as referral bias and cultural barriers, as well as difference in social support and comorbidities. This study also showed that only 6% of CAR-T cell therapy–related hospitalizations (including indications for lymphoma, MM, and ALL) were for patients from neighborhoods with a mean income under $40,000, likely because of the lack of adequate insurance coverage, high out-of-pocket expenses, and requirement of having a caregiver,[75] underscoring the disparities in access to CAR-T cell therapy. In addition to overcoming financial barriers, a systematic approach that includes streamlining referral to CAR-T centers and significant nursing and navigation support is needed to expand access to CAR-T for racial and ethnic minorities. A recent study observed that Black patients receiving standard-of-care ide-cel were more likely to develop any-grade CRS and had a longer hospital stay and prolonged cytopenias. Although the findings may be related to underlying disease burden, it potentially suggests that different strategies in monitoring and follow-up may be needed on the basis of patients' race and ethnicity.[82]

TABLE 5. Summary of Main Advantages or Disadvantages Between Allogeneic CAR-T Cells and Autologous CAR-T Cells

Autologous CAR-T Cell		Allogeneic CAR-T Cells	
Advantage	**Disadvantage**	**Advantage**	**Disadvantage**
Better expansion	Longer turnaround time	Off-the-shelf product	Complex genetic manipulation using gene-editing techniques
Longer persistence	Higher cost	Healthy donors	Lower expansion
Easier genetic modification	Higher variability between products	Higher homogeneity between products	Lower persistence
Potential lower immunogenicity	Impact of previous therapies in T-cell fitness	Lower cost (same donor = multiple products)	Inferior efficacy in the products developed so far
Absence of GVHd	Out of specification products	Multiple cell sources	Need for a more intense lymphodepleting regimen
Need for less intense lymphodepletion	Manufacturing failure	Absence of manufacturing failure or out of specification products	Delayed immune reconstitution leading to a potential higher risk of infections
Better immune reconstitution (because of the above)	Variable cell quantity	Cell quantity is controlled	Risk of immune rejection
Regulatory approval of several constructs and longer follow-up	Toxicity (CRS, ICANS, cytopenias)	Better toxicity profiles. No GVHd so far reported but short follow-up in the trials	Absence of regulatory approval so far

Abbreviations: CAR, chimeric antigen receptor; CRS, cytokine release syndrome; GVHd, graft versus host disease; ICANS, presented immune effector cell–associated neurotoxicity syndrome.

Manufacturing Time

Even after securing insurance approval, financial resources, and a spot for apheresis, long manufacturing times of 4-8 weeks for current approved BCMA CAR-T products pose a huge hurdle for CAR-T therapy. Most patients have disease that is refractory to available treatments, and waiting 4-8 weeks for manufacturing is often not feasible, even while on bridging therapy. Of all enrolled patients in the two pivotal trials that led to FDA approval of BCMA CAR-T, 9% and 14% of patients in KarMMa trial (ide-cel) and CARTITUDE-1 trial (cilta-cel), respectively, did not receive the products. Several patients have died waiting for CAR-T manufacturing, in both clinical trial and the standard-of-care setting. Potential solutions include shortening manufacturing times for currently available products through optimization of manufacturing processes and developing products with rapid manufacturing[83] or off-the-shelf allogeneic CAR-T products[68] (Table 5).

Expanding Clinical Trial Eligibility Criteria

Clinical trials of myeloma CAR-T-cell therapy have excluded patients with renal impairment, which affects a significant proportion of patients with myeloma and patients with cytopenias, central nervous system involvement, and plasma cell leukemia, with the latter two being harbingers of aggressive disease and arguably populations that might benefit significantly from CAR-T therapy. This is an area of huge unmet need. Expanding clinical trial eligibility criteria or creating special nested cohorts with CAR-T trials to allow for safety and efficacy data generation in such cohorts is critical. In addition, analysis of real-world data with standard-of-care CAR-T can also help generate preliminary data, which can then be used to advocate for access to standard-of-care therapy for these patients and inclusion of these patients in future clinical trials. As an example, in a real-world analysis of patients with renal impairment receiving intended standard-of-care ide-cel, ide-cel could be given safely to patients with renal insufficiency including one patient on dialysis, with dose adjustment of lymphodepletion chemotherapy. The incidence of CRS (89% *v* 84%) and neurotoxicity (21% *v* 19%) was comparable between patients with or without renal insufficiency. PFS was comparable (6.5 *v* 8.1 months), suggesting that patients with renal insufficiency also benefit from ide-cel.[84] As such data accumulate in above special populations, CAR-T can be given more widely and safely.

Other Immunotherapies

Many other CAR-T-cell constructs are in clinical trials for MM and may become commercially available in the future. Other types of immunotherapies, including various bispecific antibodies, are also being studied.[85] Teclistamab, which is a bispecific antibody[86] approved by FDA in October 2022, is an excellent option for patients with relapsed/refractory myeloma. Centers that are not set up for CAR-T therapy can potentially administer this regimen although they need to have expertise in the management of toxicities such as CRS and neurotoxicity. Such treatments will likely be more widely available geographically although they are still limited to tertiary care centers and patients generally require hospitalization during the step-up dosing. In the future, increasing access to bispecific antibodies through community-based practices can increase access to novel immunotherapies.

SUMMARY

In summary, CAR-T therapy has resulted in unprecedented response rates in myeloma, with two BCMA-targeted constructs approved for treatment of late relapse and several other constructs in development, including for earlier-line treatment. However, patients face several barriers to accessing CAR-T therapy and researchers, and clinicians and CAR-T manufacturers need to come together to implement solutions to broaden access to CAR-T therapy.

Frontline Management of Nodal Peripheral T-Cell Lymphomas

Henry S. Ngu, MD[1,2] and Kerry J. Savage, MD, MSc[1]

overview

Peripheral T-cell lymphomas (PTCLs) represent only 10%-15% of all non-Hodgkin lymphoma but encompass a diverse group of diseases with over 30 different subtypes. As a result of both disease heterogeneity and rarity, therapeutic progress of PTCLs has lagged behind B-cell lymphomas with very few randomized controlled studies to guide management. The most common subtypes are the so-called nodal PTCLs: PTCL-not otherwise specified (NOS), anaplastic large cell lymphoma (ALCL), and nodal T follicular helper cell lymphoma (TFHL) lymphoma, the latter of which includes angioimmunoblastic T-cell lymphoma. Anthracycline-based primary chemotherapy is still the mainstay of treatment for these common PTCL subtypes, but in recent years, we have moved into an era where more personalized therapy can be applied in some settings. Cyclophosphamide, doxorubicin, prednisone, and brentuximab vedotin CHP-BV is the first therapy in PTCL to show an overall survival benefit and represents a new standard for ALCL; however, there is less therapeutic certainty in other CD30-positive PTCLs. Recurrent mutations of epigenetic modifier genes typify TFHLs lymphomas, and collective studies demonstrate a heightened sensitivity to epigenetic therapies, leading to trials integrating these agents in the frontline setting. Molecular studies of PTCL-NOS have defined at least two subtypes, GATA3 and TBX21, the former having a poorer prognosis, but how this guides therapeutics remains unknown. Outside of ALCL, there is a growing debate as to whether trials should focus on adding a novel agent to cyclophosphamide, doxorubicin, vincristine, and prednisone (CHOP) or whether combination novel therapies should be explored in the frontline therapy setting. Finally, the role of consolidative autologous stem-cell transplant in first remission remains an area of active debate.

INTRODUCTION

Peripheral T-cell lymphomas (PTCLs) represent a diverse and complex collection of lymphomas with more than 30 different entities that share a common derivation from either a mature T or NK-cell precursor. In 2022, both the WHO fifth edition lymphoma classification update and the International Consensus Classification (ICC) published additional refinements which are largely concordant with few exceptions, including nomenclature differences[1,2] (Table 1). The so-called nodal PTCLs include peripheral T-cell lymphoma not otherwise specified (PTCL-NOS), systemic anaplastic large cell lymphoma (ALCL), and nodal T-follicular helper cell lymphomas (TFHL), representing ≈60% of all PTCLs encountered in Western populations (Table 1). With the exception of ALK-positive ALCL, the prognosis is typically poor (Table 2). Historically, treatment has been modeled after B-cell lymphomas, leading to the use of cyclophosphamide, doxorubicin, vincristine, and prednisone (CHOP) as standard therapy in PTCLs. However, it is clear that a one-size-fits-all approach is not optimal across PTCLs. In many of the rare extranodal PTCL subtypes, such as extranodal NK/T-cell lymphoma, CHOP has been abandoned.

This past decade has been a period of great advancement in PTCLs, both in understanding disease pathogenesis and in the development of new therapies tailored specifically for PTCLs. The anti-CD30 antibody drug conjugate, brentuximab vedotin (BV), demonstrated unparalleled response rates in relapsed/refractory (R/R) ALCL, and in 2018, cyclophosphamide, doxorubicin, and prednisone (CHP)-BV was approved for use in the frontline treatment of CD30-positive PTCLs. Outside of CHP-BV, CHOP remains the standard and is typically the backbone to investigate the addition of novel agents. However, with high complete remission (CR) rates seen with combination therapies, this paradigm has been recently challenged, particularly in TFHLs where a heightened sensitivity to epigenetic therapies is observed. This review will focus on these common PTCL subtypes and the current status of personalized therapy.

UPDATE ON CLASSIFICATION AND GENETICS OF NODAL PTCLs

Despite modern diagnostics, 30%-50% of patients are designated as PTCL-not otherwise specified (NOS). It has long been recognized that this is a heterogeneous group defined more by diagnostic exclusion as one of the specified subtypes. Cases of

PRACTICAL APPLICATIONS

- Nodal peripheral T-cell lymphomas (PTCLs)—peripheral T-cell lymphoma not otherwise specified (PTCL-NOS), systemic anaplastic large cell lymphoma (ALCL), and T-follicular helper lymphoma (TFHL)—are the most common subtypes in Western populations.
- Although progress in PTCLs has lagged behind B-cell lymphomas, the past decade has been a period of advancement both in understanding disease biology and therapy progress.
- Cyclophosphamide, doxorubicin, prednisone, and brentuximab vedotin (CHP-BV) is a new treatment paradigm in ALCL, but its role in other CD30-positive PTCLs remains unclear.
- TFHLs are characterized by recurrent mutations in epigenetic modifiers with heightened sensitivity to this class of agents, and recent clinical trials have integrated these agents in the treatment-naïve setting.

PTCL-NOS that are cytotoxic marker-positive (ie, TIA1, granzyme B, perforin)/EBV-positive are now called primary nodal EBV-positive T/NK-cell lymphoma (International Consensus Classification [ICC]—provisional entity) or nodal EBV-positive T and NK-cell lymphoma (WHO—HAEM5 distinct entity) (Table 1). Previous molecular profiling studies identified two main groups in PTCL-NOS by unsupervised hierarchical clustering: GATA3 with high expression of GATA3 and target genes (CCR4, IL18RA, CXCR7, and IK), resembling TH2 cells, and TBX21 (TBet) with higher expression of TBX21, EOMES, and known targets (CXCR3, IL2RB, CCL3, and IFNγ), resembling TH1 cells.[6] Although patient numbers were low, patients with a GATA3 profile had an inferior prognosis to TBX21, and subsequent genetic studies demonstrate a greater genomic complexity.[6] This dichotomization is largely captured by an immunohistochemical (IHC)-based algorithm using GATA3, CCR4, TBX21, and CXCR3(4). The IHC panel reproduced the gold standard gene expression profiling results in 85% of patients, with only 11% unclassified, and retained prognostic significance (5-year overall survival [OS] GATA3 10%-20% *v* TBX21 45%-50%).[7] Cytotoxic marker expression also delineates more aggressive disease, and almost all are of TBX21-subtype and harbor DNMT3A mutations.[8] A nanostring assay can molecularly classify the main PTCL subtypes, which may ultimately be the better tool in clinical practice.[9] As of 2023, the designation of PTCL-NOS according to these subgroups, either by molecular profiling or IHC, is not part of routine

practice and how this translates therapeutically requires additional study.

Few recurrent genetic abnormalities have been reported in PTCLs with the exception of the *t*(2; 5) (p23; q35) translocation in ALK-positive ALCL. More recently, next-generation sequencing (NGS) identified two recurrent rearrangements in ALK-negative ALCL: *P63* on 3q28 and *DUSP22-IRF4* locus on 6p25.3. Cases with *DUSP22R* have pathopneumonic doughnut cells and, by IHC, are negative for cytotoxic markers, PDL and pSTAT3. More recently, recurrent mutations in MSC^{E116K} have been identified and overexpression of the common testicular antigen (CTA) has been reported by molecular profiling.[10,11] In an initial study, approximately one third of patients with ALK-negative ALCL harbored a *DUSP22R* and had a 5-year OS indistinguishable from ALK-positive ALCL (5-year OS 90% for *DUSP22R*-positive ALK-negative ALCL *v* 85% for ALK-positive ALCL).[12] Conversely, patients with rearranged *TP63* (8%) had a 5-year OS of only 17%. Subsequent studies have demonstrated a more variable outcome for patients with *DUSP22R* ALK-negative ALCL,[13,14] which may also be affected by clinical factors as shown by a large series from the LYSA group TENOMIC database, where those with a performance status of ≥2 have a 4-year OS of only 29%.[15] Taken together, the 5-year OS ranges from 40% to 100%, and there is more limited reporting of progression-free survival (PFS; 5-year 40%-57%).[16] Patients with a relapsing remitting course and rare CNS relapse have been described.[13] The unique pathobiologic features established *DUSP22R* ALK-negative ALCL as a genetic subtype of ALK-negative ALCL in the ICC but not in the WHO fifth edition because of uncertainties around clinical behavior.[1,2] If available, FISH testing for both *DUSP22R* and *P63R* in ALK-negative ALCL should be performed (Table 1).

In the 2017 fourth edition WHO update, an expanded disease category called "angioimmunoblastic T-cell lymphoma (AITL) and other nodal lymphomas of T-follicular helper cell origin" was created to include cases with PTCL-NOS with a TFH phenotype (as identified by ≥2 of BCL6, CD10, PD1 CXCL13, and ICOS by IHC) but not having the morphologic criteria to be defined as AITL and also to include the morphologically distinct follicular type (Table 1). Nomenclature updates to these lymphomas were outlined in the ICC and WHO with minor differences (Table 1). In this review, they will be referred to as TFH lymphomas (TFHLs) and specific subtypes will be referenced as appropriate. Importantly, NGS and targeted sequencing–identified recurrent mutations in $RHOA^{G17V}$ as well as the epigenetic regulators *TET2*, *IDH2*, and *DNMT3A* occur frequently in TFHLs, and this TFH mutational profile, especially TET2 mutations, have been associated with response to epigenetic modifier therapies (see below).[17-20]

FRONTLINE COMBINATION CHEMOTHERAPY: WHAT IS THE EVIDENCE FOR CHOP IN PTCL?

Thirty years ago, the landmark SWOG phase III study established CHOP as the standard combination chemotherapy in aggressive lymphomas, including PTCLs.[21] However, it was performed in an era where diagnoses were based on the Working Formulation, and thus, the immunophenotype was not known. A few prospective and several large retrospective series have reported outcomes with primarily anthracycline-based chemotherapy in PTCL, including subtype-specific outcomes (Tables 2 and 3). Patients with ALK-positive ALCL have a more favorable outcome; however, this is in part driven by a younger age at diagnosis, and importantly, those with a high International Prognostic Index (IPI) score have a poor outcome, not unlike the other PTCL subtypes (IPI ≥3 5-year PFS range; 5-year OS 23%-33%).[27] Outcomes also tend to be better in ALK-negative ALCL, which is more evident in the clinical trial

TABLE 3. Phase III Randomized Studies in Treatment-Naïve PTCLs

Abbreviations: AATT, autologous or allogeneic transplantation in T-cell lymphoma; ALCL, anaplastic large cell lymphoma; allo, allogeneic; ASCT, autologous stem-cell transplant; CHOEP, CHOP + etoposide; CHOP, cyclophosphamide, doxorubicin, vincristine, and prednisone; CHP-BV, cyclophosphamide, doxorubicin, prednisone, and brentuximab vedotin; DHAP, dexamethasone, cytarabine, cisplatin; HDAC, histone deacetylase; IPI, International Prognostic Index OS, overall survival; PFS, progression-free survival; PTCL, peripheral T-cell lymphoma.

[a]Recruitment stopped after interim analysis showed that the study was highly unlikely to meet its primary input. Transplant-related mortality contributed to decision—103 of planned 104 patients were enrolled.

[b]Recruitment stopped because of slow accrual and a negative ACT2 study. Accrued 116 of planned 274 patients.

[c]Discovery that ALCL is universally negative for CD52 led to an amendment for exclusion.

[d]CD30-positive ≥10% of neoplastic cells (total lymphocytes may be used if enumeration of neoplastic cells not possible); by design, the study was powered to enroll approximately three-fourth of patients with ALCL.

[e]Comparison statistically significant.

setting and with the introduction of CHP-BV (see Table 3). In addition to the IPI, prognosis is also affected by recently discovered genetic heterogeneity in ALK-negative ALCL as previously described. Historically, AITL has had a similar outcome to PTCL-NOS[3,4]; however, more consistent use of autologous stem-cell transplant (ASCT) in recent years may have improved outcomes[5] (Table 2). Of note, there have been no large studies evaluating outcomes in nodal TFH NOS, and most reported studies will have included this subtype in the broader PTCL-NOS group.

There has been some debate whether anthracyclines are an essential component for cure of non-ALCL subtypes. An exploratory analysis of the International Peripheral T-cell Lymphoma Project in both PTCL-NOS and AITL evaluating the impact of anthracyclines demonstrated no significant OS difference, although power was limited, and a trend favoring the use of anthracyclines was observed for PTCL-NOS (P = .11) but not AITL (P = .48).[3] Almost all patients received anthracyclines for systemic ALCL precluding a similar analysis.[27] Although bias cannot be completely remedied, a separate retrospective study from the Mayo group did support that anthracycline use was associated with improved PFS and OS in all nodal PTCLs and the subgroup with AITL/PTCL-NOS, adjusting for the IPI in multivariate analysis.[28] With uncertainty around the importance of anthracyclines, as well as concern of pGP-mediated resistance, a number of studies emerged evaluating gemcitabine-based alternative frontline chemotherapy. The UK group compared CHOP with gemcitabine, solumedrol, and cisplatin (GEM-P) in a randomized phase II study with a 2-year PFS of 38% and 37% (P = .82) and a 2-year OS of 64% versus 51%, respectively (P = .31). Although highly exploratory, patients with PTCL-NOS (and EATL) had a significantly better outcome with CHOP (odds ratio [OR], 0.036; P = .012); in contrast, outcomes by treatment arm were similar in AITL (OR, 0.69; P = .578). The SWOG group evaluated the cisplatin, etoposide, gemcitabine, and solumedrol (PEGS) regimen in newly

diagnosed patients (and also included 21% of patients with relapsed/refractory PTCL because of poor accrual) with a 2-year PFS of only 12% and a 2-year OS of 30%.[29] These novel gemcitabine-based combinations also exclude cyclophosphamide, a highly active drug in aggressive lymphomas, and it is likely an important component. Taken together, CHOP and, in particular, cyclophosphamide and doxorubicin may be most important in ALCL and possibly PTCL-NOS, although the latter is challenged by disease heterogeneity, with less certainty in AITL.

SHOULD CHOEP BE CONSIDERED IN SOME PATIENTS WITH PTCL?

The addition of etoposide to CHOP (CHOEP) was first explored in a retrospective analysis of published German high-grade lymphoma (DSHNHL) studies (now German Lymphoma Alliance [GLA]) that suggested that it improved event-free survival (EFS) in young, good-risk (normal lactate dehydrogenase) patients; however, the benefit was most evident in ALK-positive ALCL (3-year EFS 91% *v* 57%, $P = .01$), with a trend observed in other nodal PTCL subtypes (3-year EFS 61% *v* 48.3%, $P = .057$).[30] This was an unadjusted analysis, and the findings did not translate into an OS benefit.[30] Other retrospective series have also suggested improved outcomes with CHOEP over CHOP in ALK-positive ALCL[5,31] with more inconsistent results in other subtypes. The Netherlands Cancer Registry noted improved OS in nodal PTCLs <65 years in a later era where CHOEP and ASCT were used more routinely (2009-2018 *v* 1989-2008).[5] In multivariate analysis of patients diagnosed between 2014 and 2018, a period when the regimen type was entered, a high IPI and absence of up-front ASCT were associated with an inferior OS, but the use of CHOEP did not affect outcomes. Collectively, the evidence for CHOEP is strongest in ALK-positive ALCL, but CHP-BV has largely replaced its use as outlined below. For the other subtypes, use should be restricted to younger robust patients given additional myelotoxicity.

RANDOMIZED FRONTLINE STUDIES OF CHOP-BASED REGIMENS IN PTCLs

The landmark ECHELON-2 double-blind/double-dummy phase III pivotal study evaluated CHP-BV in treatment-naïve CD30-positive PTCL.[26] Brentuximab vedotin is an anti-CD30 antibody drug conjugate linked to the antitubulin agent monomethyl auristatin E and was initially developed in both classical Hodgkin lymphoma and systemic ALCL in the relapsed setting. In R/R ALCL, the efficacy was striking with an overall response rate (ORR) of 86% and CRs observed in >50% of patients.[32] With a 5-year follow-up, 14% remained in remission in the absence of transplant, suggesting that cure was possible.[33] In the phase I study, BV was combined with CHP with omission of vincristine to avoid overlapping peripheral neuropathy.[34] ECHELON-2 compared BV plus CHP with CHOP in newly diagnosed CD30-positive PTCLs (non-ALCL PTCLs CD30 ≥10%; ALK-positive ALCL IPI ≥2; Table 3). As this was intended to be a confirmatory trial for the regulatory approval of BV in R/R ALCL in Europe and Canada, the study was designed to enroll approximately three-fourth of the patients with a diagnosis of systemic ALCL. Ultimately, 70% of patients had ALCL (ALK-negative, n = 218, 48%; ALK-positive n = 98, 22%), and consequently, the other CD30-positive PTCL subtypes are under-represented (PTCL-NOS n = 72, 16%; AITL n = 54, 12%). In the intention-to-treat group, CHP-BV was associated with improved PFS (3-year PFS 51% *v* 43%, $P < .01$) and OS (5-year OS 70% *v* 61%, $P = .04$; Table 3). PFS and OS benefits were maintained in the 5-year update (5-year PFS 51.4% *v* 43%, $P = .0.007$; 5-year OS 70% *v* 61%, $P = .042$) and driven by ALCL (5-year PFS 60.6% *v* 48.5%, $P = .0009$; 5-year OS 75.8% *v* 68.7%, $P = .053$). There was a higher incidence of acute diarrhea (38% *v* 20%) and persistent neuropathy (38% *v* 24%) with CHP-BV compared with CHOP.[26,35] The benefit of CHP-BV is not certain in PTCL-NOS and AITL subgroups, with all CIs for hazard ratios crossing 1 for PFS and OS. Of note, the study mandated that PTCLs have 10% or more CD30 staining; however, regulatory approvals were not restrictive on the basis of CD30 expression. A trial is ongoing evaluating the efficacy of CHP-BV in those with PTCL with CD30 <10% (ClinicalTrials.gov identifier: NCT04569032). With the benefit unclear for the non-ALCL subtypes, regulatory approval differs globally with FDA approval of CHP-BV in the eligible CD30-positive PTCL population, Health Canada approval in ALCL and CD30-positive PTCL-NOS/AITL, but in Europe, it is only approved in ALCL.

Despite the excellent results of CHP-BV, there is still room for improvement. Approximately 50% of patients with ALCL fail frontline therapy, mostly the ALK-negative subtype.[35] Rare CNS relapse in ALCL would not expect to be affected by BV as it has not been shown to cross the blood-brain barrier. As CHOEP is frequently used in clinical practice, a phase II study explored the safety and efficacy of CHEP-BV in 46 patients positive for CD30 (≥1%), which demonstrated an ORR of 91% and CR 80% by investigator assessment at the completion of CHEP-BV.[36] This regimen may have a role in young, high-risk patients.

Romidepsin and alemtuzumab have also been evaluated in combination with CHOP(-like) therapies in phase III trials (Table 3). Romidepsin is a selective histone deacetylase (HDAC) inhibitor and was originally approved on the basis of modest efficacy in a phase II study in R/R PTCL (ORR 25%, CR 15%).[37] A phase III study was conducted by the LYSA group investigating romidepsin plus CHOP (Ro-CHOP) versus CHOP in previously untreated PTCL, excluding ALK-positive ALCL[25] (Table 3). The addition of romidepsin

did not translate into an improved PFS in the intention-to-treat population ($P = .096$; Table 3) and was associated with increased toxicity. Unfortunately, as it was intended to be a confirmatory study, this also led to delisting of romidepsin for R/R PTCL setting in the United States and Canada, which is particularly relevant for the management of TFHLs (see below).

CD52 antigen is a GPI-linked glycoprotein that is present on normal and pathologic B and T cells and is variably expressed in PTCLs. Alemtuzumab is an anti-CD52 humanized monoclonal antibody and was combined with CHOP-14 or CHOEP-14 in phase III trials conducted by the Nordic and DSHNHL/GLA groups in younger (CHOEP-14 18-65 years ACT 1)[23] and older (CHOP14 >65 years ACT 2)[24] patients with newly diagnosed PTCLs, the former incorporating ASCT into both treatment arms (Table 3). In ACT 2, the 3-year PFS was 28% versus 29% in CHOP-A versus CHOP, respectively ($P = .248$) and the experimental arm was associated with significant toxicity. Similarly, there was no observed benefit in the ACT 1 trial (3-year EFS: A-CHOP 35% *v* 26%; Table 3).

ROLE OF CONSOLIDATIVE AUTOLOGOUS TRANSPLANT IN THE PRIMARY THERAPY OF NODAL PTCLs

In the absence of a randomized controlled study, there is a lack of uniform consensus regarding the role of high dose chemotherapy/ASCT in first remission in PTCL. Comparisons between studies are challenging because of inclusion of diverse subtypes as well as variable response to induction chemotherapy at the time of transplant. The largest prospective study was by the Nordic Lymphoma Group (NLG-T-01), which enrolled 115 patients with nodal PTCL, excluding patients with ALK-positive ALCL.[38] Depending on age, patients received CHOEP (<60 years) or CHOP-14 (>60 years), followed by high dose chemotherapy/ASCT. With a transplant rate of 70% and median follow-up of 5 years, the 5-year PFS and OS were 44% and 51%, respectively, which although unsatisfactory, appears to be better than historical expectations. In multivariate analysis, age (as a continuous variable), ALK-negative ALCL, good performance status, and absence of bone marrow involvement were associated with a more favorable outcome.

Multiple retrospective studies have also explored the utility of ASCT. A comprehensive discussion is beyond the scope of this review, but several recent studies most of which have evaluated patients in a CR are summarized in Table 4. The LYSA group performed an analysis by intent to transplant in nodal PTCLs (n = 269) where ASCT and non-ASCT groups were determined on the basis of the physician's management plan before starting induction therapy. With the analysis confined to those in a CR or PR, in multivariate analysis and with propensity score-matching, there was no PFS or OS benefit of ASCT (Table 4).[41] In contrast, in the Norwegian Cancer Registry study, omission of ASCT was associated with inferior OS in multivariate analysis. In this study, a separate 9-month landmark analysis and a sensitivity analysis evaluating only those in a CR also showed a benefit of ASCT (landmark 5-year OS 78% *v* 45% [$P < .01$]; CR-only 5-year OS 82% *v* 47% [$0 < 0.01$]). Other studies focused on patients in a CR have been mixed with some showing a benefit of ASCT,[43] but others have not.[39,40,42] Complicating interpretation, most studies have combined diverse subtypes obscuring potential subtype-specific benefit.

With uncertain benefits of ASCT, GLA and LYSA study group evaluated consolidative allogeneic SCT (allo-SCT) versus ASCT in newly diagnosed PTCL but was stopped early because of futility and similar PFS rates (3 years 43% [allo] *v* 39% [auto]).[22] Although no relapses were observed in the allo-SCT group, toxicity was high and offset any benefit[22] (Table 3).

The impact of consolidative ASCT after CHP-BV was evaluated in a subgroup analysis of the ECHELON-2 trial in patients who had achieved CR at the end of treatment with the hypothesis that a better upfront therapy may offset any benefit of ASCT[44] (Table 4). However, the PFS was better with ASCT (5-year PFS was 65.3% *v* 46.4%, hazard ratio [HR] 0.36 [95% CI, 0.17 to 0.77]; Table 4). This benefit was not evident in the CHOP arm (HR, 0.63; 95% CI, 0.32 to 1.24), although power was limited for all comparisons.[44]

Taken together, despite data limitations, consolidative ASCT is still a treatment consideration in the up-front setting; however, larger studies are needed overall to identify low-risk patients who can be managed with chemotherapy alone, and decisions should be individualized in the absence of a randomized trial. Importantly, the recently activated randomized controlled TRANSCRIPT trial in France will formally address the role of ASCT in nodal PTCLs (excluding ALK-positive) patients who are in a CR after CHOP(-like) induction therapy (CHOP, CHOEP, CHP-BV in ALCL; ClinicalTrials.gov identifier: NCT05444712).

BREAST IMPLANT–ASSOCIATED ALCL

Breast implant–associated ALCL (BIA-ALCL) was defined as a provisional entity in the 4th WHO edition and was upgraded to a distinct entity by both the ICC and WHO fifth edition update because of unique features. Although not a nodal PTCL given primary breast involvement, it is described here to highlight prognosis and management differences with classic nodal ALCL. It is elicited by a chronic inflammatory/immune reaction by the implant with secondary genetic change resulting in JAK-STAT pathway activation as well as epigenetic and cell cycle deregulation.[45] The risk of BIA-ALCL is exclusively associated with textured implants, and the time from implant to

NOTE. Estimates are rounded.

Abbreviations: AITL, angioimmunoblastic T-cell lymphoma; ALCL, anaplastic large cell lymphoma; ASCT, autologous stem-cell transplant; BV, brentuximab vedotin; CHOP, cyclophosphamide, doxorubicin, vincristine, and prednisone; CR, complete remission; CRu, CR unconfirmed; E2, Echelon-2; IPI, international prognostic index; MVA, multivariate analysis; NOS, not otherwise specified; OS, overall survival; PFS, progression-free survival; PR, partial remission; PTCL, peripheral T-cell lymphoma; UVA, univariate analysis.

[a]All exclude ALK-positive ALCL, with the exception of Abramson et al[39]: 7% ALK-positive, and Cederleuf: 19% ALK-positive.

[b]Also included extranodal-subtype enteropathy-associated TCL, hepatosplenic TCL, NK/T-cell lymphoma, primary cutaneous gamma delta lymphoma.

[C]Comparison statistically significant.

ALCL is 7-11 years. The overall risk varies in series but is likely between 1:1,000 and 1:10,000.

The most common presentation is a peri-implant effusion, and a large volume should be sent for cytology, flow cytometry including CD30, and molecular testing for a T-cell receptor clone. It is helpful to have a positron emission tomography scan before surgery as postsurgical inflammatory changes can be difficult to distinguish from lymphoma invasion. More than 85% of patients have stage I disease or disease limited to the seroma ± capsule.[46]

Implant removal with complete capsulectomy is recommended. Most are cured with surgery alone with a 5-year disease-specific survival of 95%. For those presenting with more advanced disease, the optimal management is unclear. For patients with incomplete resection, radiation may be considered, and in rare cases, BV has been given in the adjuvant setting. Although patients with BIA-ALCL were not included in ECHELON-2, CHP-BV would be reasonable in those with either lymph node or more distant disease.[46]

THE PRESENT AND FUTURE OF FRONTLINE THERAPY TRIALS IN PTCL

Integration of Epigenetic Therapy in the Frontline Setting: Is It Ready for Prime Time?

With the exception of BV in R/R ALCL, the ORR of approved agents in R/R PTCLs has been modest when considering all subtypes (Table 5). Although infrequent, long-term remissions have been reported as previously described with BV as well as with HDAC inhibitors. In the phase II registration study for romidepsin, the ORR was 25%, CR 15%, and median PFS only 3 months; however, the median duration of response was 17 months in the original report extending to 28 months with longer follow-up.[37,50] Long-term follow-up of the 27 patients with AITL enrolled in the study demonstrated an ORR of 33%, but two-third had a CR, and in four patients, it was maintained CRs for >3 years.[51] A retrospective multicenter series evaluating response to HDAC inhibitors in TFHLs versus PTCL-NOS noted a higher ORR even as a single agent (ORR/CR 56.5%/28.9% *v* 29.4%/19.6%; $P = .0035$).[52] The CR rate deepens using HDAC inhibitors in combination with other agents (ORR/CR 61.1%/38.8% *v* 25%/16.6% in TFHs *v* PTCL-NOS, respectively; $P = .072$).[52] Similar high response rates are seen in TFHL-NOS as observed in AITL. The duration of response in this study was confounded by the use of subsequent allo-SCT in many patients. Clear predictors of response are still under investigation.

Beyond HDAC inhibitors, other epigenetic therapies have demonstrated high response rates in AITL and/or TFHLs. The sensitivity of AITL to the hypomethylating agent azacitidine was first described in a retrospective series of 12 patients, five of which had an associated myeloid neoplasm. The ORR was 75% (CR 50%), and with a median follow-up of 27 months; the median PFS was 15 months, with five patients sustaining a CR for almost 2 years or longer.

Considering the frontline setting, a subgroup analysis of 201 patients with TFHL enrolled on the phase III Ro-CHOP study demonstrated an improved PFS ($P = .046$) providing additional support for enriching a trial population likely to benefit from the novel therapy. This is also highlighted in a phase II study evaluating 5-azacitidine (CC-486) administered before CHOP as priming, and although not subtype-specific, 81% of the patients enrolled had TFHLs. The CR was higher in TFHL (88% *v* 75% for all PTCLs), and with a median follow-up of 21 months, the 2-year PFS was 66%

TABLE 5. FDA-Approved Novel Agents for the Treatment of Relapsed/Refractory PTCLs

Agent	Type	Phase	Indication	ORR/CR (%)	Median DoR (months)	Median PFS (months)	Median OS (months)
Pralatrexate[47]	Anti-folate	II (PROPEL)	PTCL and transformed MF	PTCL 29/11	10.1	3.5	14.5
Brentuximab vedotin[32]	ADC CD30	II	ALCL	86%/57%	12.6[a]	12.6	Not reached
Romidepsin[b,37]	HDAC inhibitor	II	PTCL	PTCL 25/15	17[a]	4	11.3
Belinostat[48]	HDAC inhibitor	II (BELIEF)	PTCL	PTCL 26/11	13.6 —	1.6 —	7.9
Crizotinib[49]	ALK inhibitor	II	ALK-positive ALCL	88%/81%	—[c]	—	—

Abbreviations: ADC, antibody drug conjugate; ALCL, anaplastic large cell lymphoma; BV, brentuximab vedotin; CHOP, cyclophosphamide, doxorubicin, vincristine, and prednisone; CR, complete remission; DoR, duration of response; HDAC, histone deacetylase; MF, mycosis fungoides; ORR, overall response rate; OS, overall survival; PFS, progression-free survival; PTCL, peripheral T-cell lymphoma.

[a]Updated analyses: romidepsin phase II median follow-up 22.3 months, median DoR 28 months (CR, not reached); BV phase II median follow-up 58 months, median DoR 25.6 months (CR, not reached).

[b]Phase III study romidepsin plus CHOP led to withdrawal of approval of romidepsin for relapsed/refractory PTCL, in the United States, in May 2022 and in Canada March 2023.

[c]DoR assessment limited by censoring.

for all patients (69% for TFHL), with half of the patients also undergoing consolidative ASCT.[53] *TET2* mutations were associated with a more favorable PFS (P = .014), whereas the presence of *DNMT3A* trended toward inferior PFS (P = .83). Grade 3/4 neutropenia occurred in 71.4% despite GCSF use, but febrile neutropenia was 14.3%. Building on this regimen, a randomized phase II study is actively evaluating 5-aza or duvelisib (see below) in combination with CHOP (or CHOEP if <60 years) compared to CHOP/CHOEP alone (1:1:1) in newly diagnosed PTCL in CD30-negative (<10%; Alliance 051902; ClinicalTrials.gov identifier: NCT04803201).

With the potential for higher CR rates with combination therapies and uncertainties around the efficacy of CHOP, chemotherapy-free studies have emerged including in treatment-naïve patients. A phase I study of romidepsin and 5-azacitidine demonstrated an ORR of 73% in R/R T-cell lymphomas.[54] A phase II study followed in PTCL including treatment-naïve and R/R PTCL cohorts.[55] Although there were only 11 newly diagnosed patients (10 evaluable), the ORR was 70% and CR 50%. Considering all patients with TFHL (n = 27), the ORR was 80% and CR 60% and median PFS was 8. 9 months compared with 2.3 months for the remaining histologies.[55] Toxicity was not negligible, with grade 3/4 thrombocytopenia occurred in 48%, grade 3/4 neutropenia in 40%, and febrile neutropenia in 12%. Numerically, the ORR/CR rate was higher with TET2 mutations (69%/53% *v* 40%/20%); however, it did not reach statistical significance. In a separate study, romidepsin and lenalidomide were evaluated in treatment-naïve patients with PTCL ≥60 years or those <60 years and not judged to be a chemotherapy candidate.[56] Of 20 evaluable patients, 13 (65%) had AITL and the ORR was 75% (CR 30%) rising to 85% (CR 38.5%) in AITL. Long-term follow-up is needed to determine the curative potential of non-chemotherapy combination therapy options, but there is a rationale for additional study, especially in TFHLs.

FUTURE DIRECTIONS

For these common PTCL subtypes, we have moved into an era where more personalized therapy can be applied in some settings. CHP-BV is the first therapy to show an OS benefit and represents a new standard for ALCL but has an uncertain role outside of this indication. Genomic insights have highlighted recurrent mutations across TFH PTCLs, and multiple studies show consistently higher than expected response rates to epigenetic therapies with some rare long-term durable remissions. It remains unclear whether the optimal frontline trial design should be adding a novel agent to the CHOP backbone or novel therapy combinations, especially in TFHL, which shows high CR rates, and both approaches are currently under investigation. Nonetheless, modern studies are focused on integrating correlative studies to better understand who benefits from specific therapy to further move away from the one-size-fits-all approach.

Partnering With All Patients: Ensuring Shared Decision Making and Evidence-Based Management for Underrepresented Groups With Multiple Myeloma

Claudio Cerchione, MD, PhD[1]; Shakira J. Grant, MBBS[2]; and Sikander Ailawadhi, MD[3]

overview

Several landmark therapeutic advances in multiple myeloma (MM) have led to an unprecedented number of options available to patients and their physicians as shared decision making is attempted. A myriad of factors need to be considered to ensure that patient-, disease-, and treatment-related factors are addressed to arrive at the most appropriate choice for patients at that time in their journey with myeloma. Some of these factors have traditionally remained underaddressed but have a clear association with patient outcomes, leading to underrepresented groups of patients with MM, including the elderly patients, racial-ethnic minorities, and those with specific advanced comorbidities, for example, renal insufficiency. Some of these factors may not be modifiable, but data suggest that they may give rise to implicit or explicit bias and affect treatment decisions. A growing body of literature is bringing these factors to light. However, their incorporation in day-to-day decision making for patients needs to be universal. It is imperative that prospective data are generated for all these and other underrepresented groups such that evidence-based medicine is applicable universally to all patients with MM, irrespective of clinical and sociodemographic factors.

INTRODUCTION

As the understanding and management of multiple myeloma (MM) evolve, considering various patient-, disease-, and treatment-related characteristics to arrive at the most evidence-based, patient-centric decision is imperative. Figure 1 summarizes some of these factors to be considered for informed decision making with patients. Several of these factors are modifiable, whereas others may not be. Practicing evidence-based medicine is associated with superior outcomes in patients.[1] Yet, considering all the patient-, disease-, and treatment-related factors to take the most appropriate evidence-based decision is challenging. Management guidelines for MM have several options available for patients.[2] Previous studies have shown that there are several traditionally underserved and underrepresented patient groups, including older adults, racial-ethnic minorities, and patients with certain comorbidities, for example, those with renal dysfunction. These groups have traditionally not been included in clinical trials; thus, they did not have uniform management guidelines, hence not realizing the true benefit of medical advancements. Partnering with patients to achieve shared decision making, accessing the most appropriate and timely standard-of-care therapeutics, and optimizing clinical trial participation can help MM patient groups on the fringes of health care delivery get included under the umbrella of evidence-based management.

MANAGING MM IN OLDER ADULT POPULATIONS

Age-Related Disparities in MM Incidence and Outcomes

MM is an incurable plasma cell malignancy with incidence and mortality rates disproportionately burdening older adults. With a median age at diagnosis of 69 years, approximately 60% of all newly diagnosed patients will be 65 years and older.[3] Older age at diagnosis means many will also have functional deficits and complex medical comorbidities affecting treatment delivery and tolerability.[4,5] Furthermore, these same older adults are challenged when accessing care because of structural barriers, including lack of transportation, lack of caregiver or other forms of social support, and the influences of ageism which the WHO defines as the "*stereotypes, prejudice, and discrimination towards others or oneself based on age.*"[6,7] Cumulatively, these factors contribute to poor patient-centered outcomes such as quality of life, physical function, and psychological well-being.

Although several potential barriers may limit health care access for an older adult with MM, the unprecedented number of novel therapies and those in the development pipeline have provided increasingly more

Author affiliations and support information (if applicable) appear at the end of this article.

PRACTICAL APPLICATIONS

- The approach to managing older adults with multiple myeloma (MM) requires key consideration of disease- and aging-related factors (assessed using a geriatric assessment or frailty indices) and other facets, such as ageism, which could further limit this population's access to high-quality care.
- Patients' race-ethnicity is not a traditional factor to consider for shared decision making or while generating prospective evidence for MM management, but ample data show that how management decisions are made and how patients access or use health care affect outcomes.
- Patients with MM and advanced comorbidities are frequently excluded from clinical trials, and they may not have an optimal duration of treatment because of lack of appropriate management of adverse events, leading to an impact on their outcomes. A concerted effort to mitigate and manage comorbidities is necessary to provide optimal, evidence-based management and realize the true benefit of therapeutic advancements in all patients.

available treatment options for this population. On the basis of SEER17 2012-2018 data, we have seen an increase in the percentage of people surviving 5 years after a MM diagnosis (relative survival) to 58%. However, there is still a survival gap that exists between older (65 year and older) and younger (younger than 65 years) adults with MM, resulting in only 40% of older adults being alive at 5 years after a MM diagnosis compared with 69% of younger adults with MM. Furthermore, the percentage of early deaths (ie, within 6-12 months of diagnosis) in MM is greatest for older adults.[8] In a recent analysis of 7,512 adults with newly diagnosed MM (NDMM; 2011-2021) and treated primarily in community-based practice settings, 8.3% of adults died within 6 months of diagnosis, with 73% of early deaths occurring in those who are 70 years and older.[9] The disproportionate burden of early and late deaths for this population highlights the growing urgency to address the myriad factors, contributing to the poor survival rates for older adults with MM.

Impact of Ageism

Ageism is prevalent and is associated with poor physical and psychological health outcomes.[10] Among 2,035 predominantly White (71%) community-dwelling adults age 50-80 years participating in the National Poll on Healthy Aging, 94.4% reported regularly experiencing one or more forms of everyday ageism.[10] Although less attention has been given to the effects of ageism in MM, the recent overt and more subtle examples of ageism highlighted during the COVID-19 pandemic (eg, prioritization of COVID-19 resources and the allocation of intensive care unit resources, including ventilatory support during the pandemic's peak, where resources were limited) emphasize the growing and urgent need for more research focused in this area.[11,12] Specifically, in the context of MM, effects of ageism can be viewed through the continued underrepresentation of older adults with MM in clinical trials because of age-based and other restrictive eligibility criteria, as well as provider bias affecting whether these older adults are given the option to enroll in a clinical trial.[13,14] In addition, African American (AA) patients

FIG 1. Informed decision making. Main categories and some specific examples of factors to consider for informed decision making with patients and their caregivers while making evidence-based decisions for patients at any stage of disease.

with MM have incidence (AA: 14 per 100,000 *v* White: 6 per 100,000) and death rates (AA: 6 per 100,000 *v* White: 3 per 100,000) that are twice their White counterparts.[15] These stark disparities create a double disadvantage for older AA patients with MM, who, in addition to the disease- and treatment-related impacts, must also navigate the interactive effects of ageism and structural racism (defined as the unavoidable and unfair inequalities in power, resources, capacities, and opportunities across racial or ethnic groups).[12,16,17]

Management Considerations Among Older Adults With MM

The management of older adults with MM is very complex and requires consideration of not only disease-related characteristics but must incorporate a global assessment of older adults' health, including their treatment preferences and goals (Fig 1). The Comprehensive Geriatric Assessment (CGA) is considered the gold standard in geriatric medicine, capable of capturing the heterogeneity of aging. The CGA assesses multiple domains, including cognition, comorbidities, physical function, polypharmacy, psychological health, social support, and environmental and spiritual components that can affect an older adult's health.[18] This multidisciplinary effort facilitates developing a coordinated care plan informing oncologic care, including participant eligibility in clinical trials.[18,19] In the real world, implementation and dissemination barriers challenge the operationalization and acceptance of CGA-guided approaches and subsequent recommendations.[20] To address these barriers, abbreviated tools such as the International Myeloma Working Group's (IMWG) frailty score,[21] Revised Myeloma Comorbidity Index (R-MCI),[22] and the Facon simplified frailty scale[23] among others have been developed (Table 1). These tools estimate an older adult's fitness level, which occurs on a spectrum ranging from fit to frail. When applied to older transplant-ineligible populations with MM, these frailty scores can predict treatment toxicity, rates of treatment discontinuation, progression-free survival (PFS), and overall survival (OS).[22,29] In the clinical trial setting, these tools are increasingly incorporated to assess the fitness status of patients and, in some circumstances, test fitness-based approaches to assigning MM therapies.[30] A recent systematic review evaluating frailty prevalence and the outcomes of frail patients with MM enrolled in clinical trials found that 42% of trials used the IMWG frailty score and demonstrated high variability in frailty prevalence ranging from 25.1% to 54% in the newly diagnosed setting.

TABLE 1. Myeloma Fitness/Frailty Risk Scores

Frailty Score	Geriatric Domains	Study Design for Score Development	Study Sample Size	Biological Marker	Score Range	Interpretation
IMWG[24]	ADLs IADLs CCI	Retrospective	869	None	0-2	0 (fit) 1 (intermediate fit) 2 (frail)
R-MCI[22]	Age Fried Frailty Lung function Renal function Karnofsky Performance Index	Prospective	801	None	0-9	0-3 (fit) 4-6 (intermediate fit) 7-9 (frail)
Facon Frailty Scale[25]	Age CCI ECOG performance status	Retrospective	1,618	None	0-1 ≥2	1-1 (nonfrail) ≥2 (frail)
Myeloma Research Alliance Risk Profile[26]	Age WHO performance status	Retrospective	2,372	CRP ISS	<−0.256 −0.256 to −0.0283 >−0.0283	<−0.256 (low risk) −0.256 to −0.0283 (medium risk) >−0.0283 (high risk)
Mayo Frailty Index[27]	Age WHO performance status	Retrospective	351	NT-proBNP	0-3	0 (stage 1) 1 (stage 2) 2 (stage 3) 3 (stage 4)
Ancona Vulnerability Score[28]	CCI WHO performance status	Retrospective	266	None	0-2	0 (low) 1 (intermediate) 2 (high)

Abbreviations: ADLs, activities of daily living; CCI, Charlson Comorbidity Index; CRP, c-reactive protein; ECOG, Eastern Cooperative Oncology Group; IADLs, instrumental activities of daily living; IMWG, International Myeloma Working Group; ISS, International Staging System; NT-proBNP, N-terminal pro-brain natriuretic peptide; R-MCI, Revised Myeloma Comorbidity Index.

In comparison, trials in the relapsed/refractory MM (RRMM) setting noted frailty prevalence as high as 73.6%.[25]

Moving Beyond Frailty Scores to Examine Additional Barriers to Care for Older Adults With MM

Despite MM-specific tools such as those noted above and their ability to shape understanding about the heterogeneity in aging phenotype across MM, these tools also have their limitations. One, in particular, is the use of chronologic age within these scoring systems, which is counter to the narrative that chronologic age should be considered separate from biological/functional age and is not a good surrogate for predicting those likely to have the worse MM-related outcomes. Furthermore, using the Charlson Comorbidity Index in the R-MCI could omit MM-specific comorbid conditions.

In clinical practice, we must also consider additional factors, such as an individual's goals and treatment preferences, life expectancy, presence of caregiver support, and other structural barriers to health care access, such as lack of transportation, financial concerns because of under/uninsured status, and fixed/limited incomes in older adults, that could affect their ability to pay for medical services including MM-related and supportive therapies. Furthermore, beyond individual-level factors, we must also acknowledge and find strategies to overcome the effects of ageism. Emerging data, such as a 2022 publication by Allen et al,[10] demonstrate in a national survey of older adults that with an increasing number of everyday ageism–related events, the odds of fair or poor physical health increased by 1.13-fold (95% CI, 1.01 to 1.17; $P < .001$). Furthermore, adults age 65 years and older are more likely than their younger counterparts to have a larger mean amount of everyday ageism (mean, 11.23 [95% CI, 10.80 to 11.66] *v* 9.55 [95% CI, 9.26 to 9.84]; $P < .001$). These findings highlight the potential for compounded harm that results in poor health outcomes among older adults with MM, especially those with advanced chronologic age and low socioeconomic status (SES). Further adverse health outcomes among this population, particularly for older AA adults, can be caused by the effects of structural racism.[24]

Managing MM in Older Adults Requires Acknowledging and Addressing MM and Age-Related Clinical Factors, Social Determinants of Health and the Effects of Ageism, and Structural Racism

Managing an older adult with MM is complex and requires careful consideration of several competing factors. Multilevel and potentially multidisciplinary approaches are necessary to ensure optimal and equitable outcomes for this population. These approaches must be personalized to ensure the ability to deliver tolerable, high-quality MM care that provides maximal therapeutic benefit while preserving function and quality of life. A biomarker-driven approach represents only one dimension of care capable of risk-stratifying patients. Although several studies are underway evaluating high-risk patients with MM, the definitions used across studies vary based on gene expression profile signatures and single or combination genetic abnormalities (eg, double-hit MM).[31] However, for older adults, especially those considered frail, a biomarker-based approach to treatment can potentially lead to overtreatment of these individuals, resulting in treatment-related toxicities, early treatment discontinuation, and declines in overall health and quality of life. Instead, these biomarker-based approaches must be merged with assessments of frailty and other geriatric domains (eg, social barriers to care and the presence of social support) to drive more equitable outcomes for this population.

Treatment Options for Older Adults With MM in the Newly Diagnosed and Relapsed Settings

The range of therapeutic options has continued to increase for older adults who are fit but otherwise ineligible for an autologous stem-cell transplantation (ASCT). These include the daratumumab-based triplet regimen: daratumumab, lenalidomide, and dexamethasone (D-Rd). In the most recent update of the MAIA trial presented during the 2022 American Society of Hematology's annual meeting, after a median follow-up of 64.5 months, PFS was improved with D-Rd versus Rd (median, 61.9 *v* 34.4 months; hazard ratio [HR], 0.55; 95% CI, 0.45 to 0.67; $P < .0001$). Furthermore, the median OS was not reached with D-Rd versus 65.5 months with Rd (HR, 0.66; 95% CI, 0.53 to 0.83; $P = .0003$).[32] Importantly, among those enrolled in the MAIA trial, the median age was 73 years in the D-Rd arm versus 74 years in the Rd arm; 44% of participants were 75 years and older.[32] Subsequently, Facon et al retrospectively assessed the frailty status (IMWG frailty score) of MAIA participants. In the D-Rd arm, 47% were considered frail versus 46% in the Rd arm. Although the median PFS at 36 months was longer for frail patients receiving D-Rd compared with Rd (not reached *v* 30.4 months; HR, 0.62; $P = .003$), it remained shorter than the median PFS observed for nonfrail patients in either arm (not reached *v* 41.7 months; HR, 0.48; $P < .0001$).[33] The data of this trial also underscore the positive focus on including elderly patients with MM in ongoing clinical trials, with some forthcoming clinical trials in the United States specifically focused on this population (S2209; ClinicalTrials.gov identifier: NCT05561387).

Alternative treatment options that could be considered for an older fit adult include the triplet regimen of bortezomib, lenalidomide, and dexamethasone (VRD) on the basis of data from the SWOG S0777 study.[34] However, bortezomib use among older adults requires careful consideration of the toxicity risk. Especially relevant to older adults are neuropathy and the risk of falls. In an analysis of 2,052 older adults with

NDMM, bortezomib was associated with a 36% increased risk of falls (adjusted HR, 1.36; 95% CI, 1.05 to 1.75; $P = .018$).[35] Given these concerns about toxicity, dose-adjusted VRD (VRD-lite) could be considered an alternative treatment approach for some older adults. For those with NDMM and considered to have intermediate fitness, dose-adjusted Rd-R (ie, Rd, followed by maintenance lenalidomide) could be considered.[36] In the relapsed setting, data remain limited, especially for those considered frail using the existing standardized scores (eg, IMWG frailty score). Of further concern are the tolerability of these subsequent lines of therapy and the need for early discontinuation. For example, in the ICARIA study of isatuximab, pomalidomide, and dexamethasone versus pomalidomide and dexamethasone, pomalidomide was reduced in 43% of patients and 335 required reductions in dexamethasone.[37] Furthermore, although studies such as ARROW,[38] ENDEAVOR,[39] and ASPIRE[40] included 25% to 35% of patients considered frail on the basis of the IMWG score, the rates of grade $\geq$3 treatment-emergent effects and cardiac events were higher among the frail population.

Role of Autologous Stem-Cell Transplantation in Older Adults

ASCT remains an integral treatment option for MM, with the existing literature demonstrating improvements in PFS when used in frontline settings.[41] Historically, clinical trial data evaluating the role of ASCT were focused on younger (younger than 65 years) and more fit individuals.[42] However, a growing body of literature demonstrates increasing ASCT use in older adults, particularly those who were 70 years and older.[43] For example, Munshi et al,[43] in an analysis of 2,092 patients 70 years or older registered in the Center for International Blood and Marrow Transplant Research database, showed identical outcomes between older and younger patients who received a single dose of melphalan 200 mg/m^2. However, survival estimates were lower for those who received a single dose of dose-reduced melphalan (140 mg/m^2), a finding attributed to coexisting medical comorbidities. These data are encouraging and can be used to guide provider discussions about the role of ASCT in select older adult populations. Furthermore, providers must be aware of other factors such as insurance status, lack of caregiver support, and, importantly, patient preference as these can also help shape decision making regarding ASCT in older adults.

In the future, ongoing studies such as the phase III Frailty-adjusted therapy in Transplant Non-Eligible patients with newly diagnosed Multiple Myeloma (FiTNEss [UK-MRA Myeloma XIV Trial]),[44] could help address important questions about the role of frailty-adapted approaches for older adults with NDMM. However, more studies are needed to shape the existing therapeutic approaches, including newer cell-based therapies for older frail adults in the relapsed setting.

REAL-WORLD IMPACT OF RACIAL-ETHNIC DISPARITIES IN MM

Although patient race-ethnicity is not traditionally taken into account to arrive at informed, evidence-based management decisions for patients with MM, there is ample evidence that patient race-ethnicity can significantly affect their access to and utilization of health care resources.[45] This can then indirectly affect outcomes, including morbidity and mortality from the disease. Although the incidence of MM is twice in AA patients as compared with White patients, the prevalence pool overwhelmingly comprises White patients.[46] AA patients make up approximately 20% of all patients with MM in the United States. Thus, the vast understanding of MM characteristics, management, and outcomes is among White patients, with gross underrepresentation of racial-ethnic minorities. A focused understanding of MM in AA patients and other racial-ethnic underserved groups is warranted.

Clinical and Biological Characteristics

Several studies have suggested that disease biology and clinical characteristics may be distinct for patients from various racial-ethnic groups.[45,47-49] Patients with MM and African ancestry have been reported to have a lower incidence of certain high-risk mutations, for example, TP53, t(14;16), t(14;20), as compared with their European counterparts.[48,49] At the same time, t(11;14) mutation, which is not considered high-risk, but can have a therapeutic implication with B-cell lymphoma 2 targeting, is seen more frequently in AA patients.[48] Any significant cytogenetic differences have not been reported so far in Hispanic patients as compared with the reference population of White patients.[50] Thus, if there was an exclusive biologically driven therapeutic landscape, AA patients may be expected to have superior survival as compared with White patients, which has not been universally reported, suggesting a larger impact of health care access and utilization. Concerted, prospective efforts to confirm such findings on a large scale, with populations who are enriched for racial-ethnic minorities, are necessary to arrive at firm data and use that to inform therapeutic decisions. Clinical characteristics have been explored among racial-ethnic groups in large databases and show that AA patients are significantly younger than White patients at the time of MM diagnosis and Hispanic patients are even younger as compared with AA patients.[51] This can lead to a difference in age-associated comorbidities, insurance eligibility, and occupation. These in turn can influence treatment choices and eligibility for ASCT, which is considered standard of care for MM in younger fit patients.[52] It has also been reported that myeloma-defining events and myeloma-related complications (hypercalcemia, anemia, and kidney dysfunction) are seen more frequently in AA patients as compared with other

racial-ethnic groups.[45,53] Of note, AA patients are least likely to have myeloma-related bone fractures, considered due to higher bone density seen in them as a race.[45] These findings can be used to triage health care resource utilization and institute targeted interventions. This can also inform timing and choice of therapy in some cases.

Access to and Utilization of Care

Several studies using large national databases including claims data have shown that racial-ethnic minorities have a disparate access to treatment modalities considered cornerstones of MM management, for example, novel therapeutic agents (proteasome inhibitors [PIs], immunomodulatory agents) and SCT. Although the overall utilization of novel therapeutic agents and SCT have increased among all racial-ethnic groups over time, the relative increase has been lesser among AA and Hispanic patients.[45,54,55] Various SCT-focused analyses have reported lowest rate of utilization among Hispanic patients[56] and the age-adjusted odds of receiving SCT being lower among AA patients (as compared with White patients).[57] In another study looking at single-center referral patterns, it was seen that AA patients are referred for a SCT significantly later in their disease course than White patients.[58] Although individual studies may have shown varied results, the undercurrent is that AA and Hispanic patients have lesser and delayed SCT utilization as compared with White patients. Timely utilization of SCT has a significant association with improved PFS in MM,[52] and as such, a delay in receiving SCT or failure to use this modality altogether can lead to inferior outcomes for AA and Hispanic patients with MM.

Similar to SCT utilization, timely access to and utilization of novel therapeutic agents have been the focus of several large studies. As for SCT, the use of novel agents has increased for all patients over time, but the increase in racial-ethnic minorities has been significantly lesser.[55] Furthermore, AA and Hispanic patients have a longer time from MM diagnosis to novel therapy initiation versus White patients (median, 5.2 and 4.6 *v* 2.7 months, respectively).[55] Evaluating some of the novel agents individually, rather alarming trends were noted including significantly delayed initial treatment with bortezomib among Hispanic patients (median, 117 *v* 46-51 days for other races; $P = .025$), no significant increase in the use of lenalidomide among Hispanic patients, and no significant increase in the use of bortezomib among Asian patients.[54] Even after controlling for overall health and potential access barriers, AA patients with MM are significantly less likely to be treated with bortezomib, leading to a potential association with increased hazard of death.[59] Patient race-ethnicity is also associated with disparate patterns of care, including underuse of maintenance therapy and frequent interruptions in treatment among minorities.[60] A major advancement in MM therapeutics has been the approval of chimeric antigen receptor-T (CAR-T) and bispecific antibody treatment, bringing forth a new era of immunotherapy, using T-cell–targeted and engaging agents. Although data on the use of these agents by race-ethnicity are not mature yet, some recent reports presented only in abstract form so far are suggesting at least initially a dismal rate of utilization by racial-ethnic minorities.

Although there may be a complex interplay of factors that are associated with these management patterns and disparities, demonstrating them helps us understand some of the core issues, which can potentially be addressed for universal access to evidence-based care.

Clinical Trials Participation

Clinical trials represent the advancements in medicine and provide access to novel therapies, leading to improvement in PFS and OS over the prevailing standard of care. The need for adequate representation of a diverse patient population in clinical trials is imperative for widespread generalizability of study results. Yet, studies have shown that racial-ethnic minorities are underrepresented in cancer clinical trials, and their accrual rates have not necessarily increased in a meaningful way over time.[53,61,62] This has led to most of the clinical trial participation and, as a result, the knowledge about drug/regimen safety and efficacy stemming from studies among White patients. Specific analyses in MM have shown a similar trend of racial-ethnic minorities being underrepresented in clinical trials.[63] This trend becomes more pressing in MM because of the higher incidence in AA patients and despite that clinical trials falling short of representing the true demographic of patients with MM in the country. The true nature of this disparity becomes evident when these drugs/regimens are used in a widespread populace, and differences in efficacy or toxicity are noted among patients of different racial-ethnic groups, with the lack of prospective clinical trial benchmark data among racial-ethnic minorities.[64-66] Within MM care, there has been widespread attention to this, with some of the recent large clinical trials showing better success in enrolling racial-ethnic minorities. Of note, although a lot of ongoing attention in this field is for AA patients with MM, it would be a missed opportunity to not address other underrepresented groups, for example, Hispanic patients, elderly patients, and those in rural areas. It is likely that several of the similar sociodemographic factors affect these other underrepresented groups as well, just like AA patients with MM. Regulatory, advocacy, academic, and patient support groups, among others, are bringing more attention to the obvious issue of health care disparities in MM care and cancer management at large. Ongoing efforts are aiming to address these disparities by designing clinical trials with more inclusive eligibility criteria and bringing trial access to traditionally underrepresented institutions, which may be

enriched in racial-ethnic minority patients, such that those who are traditionally underrepresented can get a fair shot at clinical trial participation.

Financial Toxicity

SES is an interplay of several sociodemographic factors. It has been postulated that SES of racial-ethnic minority patients with MM affects their OS, presumably because of differences in access and utilization of health care resources.[67,68] It has also been shown that the cost of care is disproportionately higher among racial-ethnic minorities, potentially leading to an intertwined vicious circle of worsening SES. Medicare claims have been reported highest during first 6 months after MM diagnosis for AA patients and at any time after MM diagnosis for Hispanic patients.[35] Over time, Medicare claims have been reported to increase most steadily for Hispanic patients ($P < .001$).[35] In another analysis, the mean adjusted all-cause inpatient, medical, and total monthly costs were significantly higher among Hispanic patients compared with White patients, showing a higher burden of the cost of care on ethnic minorities.[55]

Outcomes

Racial-ethnic disparities in health care access and utilization for patients with MM have been reported extensively. The relationship between patient race-ethnicity and outcomes in MM, both PFS and OS, is an important focus of research. Two findings have been reported in various analyses: (1) OS and myeloma-specific survival (MSS) are different for patients with different race-ethnicities and (2) in equal opportunity situations, for example, clinical trials, single institutions, or Veterans Administration (VA) system, racial-ethnic minorities may have similar or even superior outcomes.

Before other data being available about disease biology and health care access, OS and MSS were noted to be superior in AA patients as compared with White patients. Hispanic patients were noted to have the worst OS in population-level analyses.[51] Other studies also showed superior MSS in AA patients, but OS differences were not noted.[55] If differences in disease biology, as noted above, were the main driver of outcomes, AA patients would be uniformly noted to have superior OS than White patients. Thus, access and utilization seem to be more impactful on disparate outcomes. Pooled analysis from National Cancer Institute–sponsored MM clinical trials showed that despite differences in presentation, disease burden, and risk factors, outcomes (OS and PFS) of White patients and racial-ethnic minorities were similar, suggesting that equal access settings such as clinical trials can benefit outcomes in MM.[53] Subsequently, survival for younger AA patients considered SCT-eligible was reported to be superior to White patients in a large analysis conducted in the VA system.[69] Survival advantage was not noted in the older population, suggesting other factors at play. A more recent analysis from the SEER-Medicare database shows that in a matched cohort analysis, AA patients have better OS than White patients when treated equally, reiterating the importance of providing equal access opportunities to racial-ethnic minorities, the traditionally underserved group.[70]

TREATMENT OPTIONS IN PATIENTS WITH MM AND RENAL IMPAIRMENT

Relevance of Renal Impairment in MM

According to the novel IMWG criteria for symptomatic MM, the definition of renal impairment (RI) is based on either elevated serum creatinine (sCr; >2 mg/dL) or reduced creatinine clearance (CrCl; <40 mL/min), which must be the result of myeloma.[71] At the time of diagnosis, when evaluated by sCr or CrCl, the incidence of RI has been reported at 20%-40%, with a slightly higher proportion over the course of the disease because of worsening of renal function due to the natural history of MM.[72,73] Overall, an acute renal involvement is an independent adverse prognostic factor with a negative impact on OS for patients with MM, especially in terms of increased risk of early deaths and infections.[74] The average level of renal function among general population older than 70 years is at or below the threshold used to define chronic kidney disease (CKD) with an estimated glomerular filtration rate <90 mL/min.[75,76] Therefore, since aging is associated with a gradual deterioration of renal function, the possibility of having patients with MM and also preexisting RI is consistent and notably higher in elderly patients. The elderly population with CKD is representative of a frail group of patients who are more prone to develop renal injury from myeloma and its treatment and are universally underrepresented in clinical trials. A large observational cohort study demonstrated that patients with MM and CKD had an increased risk for mortality, delay in initiating next line of therapy, and incidence of anemia, hypercalcemia, and progression of CKD as compared with patients with MM but without CKD.[77]

Physiopathology of Myeloma Kidney

This etiology of renal injury in patients with MM (myeloma kidney) has been well-described as a secondary event due to multiple clinicopathologic mechanisms involving monoclonal free light chains (FLCs), leading to damage of the renal structures, first in the renal tubules and subsequently in the interstitial space and glomeruli.[78] The foremost final mechanism of kidney disease is the so-called cast nephropathy where the overproduction of FLCs causes direct proximal tubular injury and indirect cast-mediated damage.[79] The interaction of light chains with tubular cells leads to chronic tubulointerstitial inflammation triggered by light chains endocytosis, inducing the release of interleukin-6 (IL-6), IL-8, and monocyte chemoattractant protein-1, finally resulting in NF-kappa-B

intracellular proinflammatory pathway activation.[80] Histologic features seen typically are chronic tubulointerstitial nephritis with distal tubule metachromatic casts (composed of mixed light chains and Tamm-Horsfall protein), frequently surrounded by syncytial giant cells/polymorphonuclear reactive infiltrate.[81]

Supportive Care and Mechanical Approaches

Cornerstones of RI in MM in the emergency setting are adequate hydration and hypercalcemia control (Fig 2). Fluid administration (approximately 2 L/m^2/d) is essential to temporarily dilute clonal light chains concentration in the tubules, decreasing their potential role in inducing cast formation.[82] Potentially nephrotoxic agents such as nonsteroidal anti-inflammatory drugs, loop diuretics, aminoglycosides, angiotensin-converting enzyme inhibitors, or angiotensin II receptor inhibitors should be avoided or withdrawn. Bisphosphonates are essential compounds necessary to prevent and manage MM-related bone disease but have a well-known potential nephrotoxicity because of the possibility of inducing tubular necrosis. Therefore, zoledronic acid and pamidronic acid should be administered carefully in an RI setting and only when CrCl is higher than 30 mL/min while clodronic acid only when CrCl is more than 12 mL/min.[83] In patients with end-stage renal disease who need supportive treatment for bone disease, the fully human monoclonal antibody (MoAb) against RANKL denosumab is alternatively indicated.[84] High cutoff dialysis with a protein-leaking dialyzer (Gambro HCO 1100 dialyzer) can improve the clearance rate of FLC with a theoretical FLC reduction of 35%-70% in the first 2 hours, followed by a gradual reduction in efficacy by a re-equilibration effect because of FLC concentration rebound by other biological compartments.[85] Nevertheless, a randomized trial did not show any significative differences between conventional and high cutoff dialysis, causing questions that remain on the optimal strategy, and the true efficacy of this method for renal recovery in patients with MM.[86] There are no consensus guidelines on the approach for renal replacement therapy (RRT) approach in RI in patients with MM, but it is recommended that RRT should be initiated (in addition to specific anti-MM treatment) as soon as possible, with the

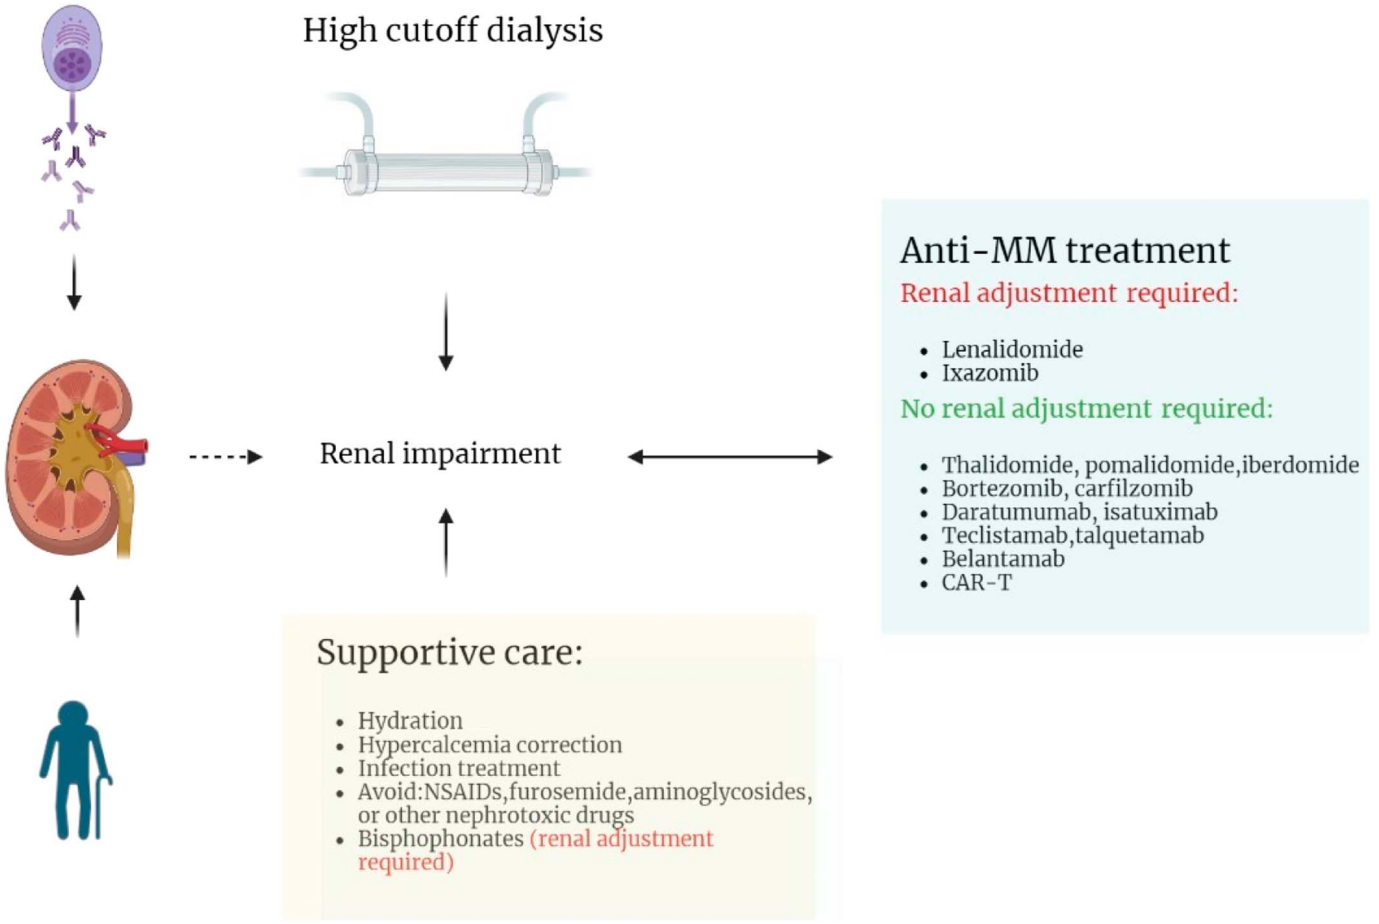

FIG 2. RI in MM. Pathophysiology of disease and factors to consider for management of RI in patients with MM. CAR-T, chimeric antigen receptor-T; MM, multiple myeloma; NSAIDs, nonsteroidal anti-inflammatory drugs; RI, renal impairment.

number of sessions possibly guided by the goal of holding FLC below 500 mg/L, a threshold for triggering tubular injury.[87] Overall, there is a trend toward better renal outcomes with the use of high cutoff dialysis, but no clear data are available on long-term renal and general outcomes because of the lack of randomized clinical trials.[88]

Immunomodulatory Drugs and PI in MM and Renal Insufficiency

Thalidomide is the first-in-class among the immunomodulatory drugs (IMIDs), initially adopted as a single agent and now part of combined induction treatment, with a wider utilization ex-US. Its pharmacokinetics are not affected by renal function impairment since clearance parameters of patients with renal failure are very similar to those reported in patients with normal renal function, and there is no need to modify its dose during dialysis.[89] Lenalidomide, a second-generation IMID, widely adopted in both transplant-eligible and noneligible patients with MM, has a relevant renal excretion requiring dose adjustment in relation to renal function, as moderate, severe, or end-stage renal disease impairs its excretion.[90] Lenalidomide-based regimens have been documented as effective in patients with RI, but with careful CrCl monitoring, as the major toxicity (hematologic) is directly related with impaired lenalidomide renal clearance.[91] A 2011 consensus statement is still a thorough guide for clinicians regarding managing lenalidomide dose (independent of the combination treatment adopted) by CrCl level.[92] The third-generation IMID, pomalidomide, is poorly excreted by kidneys (about 2%), and patients with RRMM even with moderate, severe, or advanced RI show comparable efficacy and safety profile, with a 4-mg recommended starting dose.[93] Iberdomide, a novel CelMod, is not currently FDA-approved, and its activity and safety profile in impaired renal function patients are currently being explored (ClinicalTrials.gov identifier: NCT04933747). Regarding PIs, the first-in-class bortezomib has mainly a hepatic metabolism, with only inactive metabolites undergoing renal excretion.[94] Rapid reduction of disease burden and no significant renal metabolism result in high overall response rates and renal response (reversibility on injury) from this agent.[95,96] Moreover, bortezomib-based treatment is associated with a significant probability of a rapid renal response even in patients under dialysis because of myeloma kidney, with improved survival of patients who became dialysis independent.[97] The second-generation PI, carfilzomib, as well has no influence of renal function on pharmacokinetic parameters, with no need for dose adjustment even in advanced RI.[98] A warning about rare and unpredictable non–myeloma-related renal injury (thrombotic microangiopathy, albuminuria >1 g/day and at least grade 3 acute kidney injury) has been reported.[99] Regarding the only orally available PI, ixazomib, the incidence of grade 3 and 4 adverse events in patients with severe RI or those on dialysis advocates using a reduced dose of 3 mg (instead of 4 mg) in these patients.[100]

Immunotherapy Does Not Get Affected by Renal Function

The treatment of MM has been further revolutionized by the introduction of immunotherapy. This class of drug comprises antibodies with both a targeted action and an indirect immune system (T cells) redirection against MM cells. The significant advantage of these agents is that on the basis of data so far, response rates and PFS with them are not affected by impaired renal function from MM.

Daratumumab and isatuximab are anti-CD38–directed humanized immunoglobulin (IgG) MoAbs with remarkable efficacy in patients with both NDMM and RRMM in combination with dexamethasone, PIs, or IMiDs. Anti-CD38 MoAb administration leads to rapid myeloma cell death by several mechanisms (complement-mediated cytotoxicity, antibody-dependent cytotoxicity, etc). A rapid drop in FLCs after daratumumab administration, with no negative impact on safety even in patients with severe renal injury, has made this agent fundamental in treating RI in MM.[101] Data have now been reported regarding the safety and maintained efficacy of daratumumab in terms of OS, PFS, and MRD-negative rate among both patients with normal and impaired renal function (ClinicalTrials.gov identifier: NCT01985126). Isatuximab, another IgG1 MoAb with a different CD38 target epitope, is a very active anti-MM agent combined with pomalidomide (or carfilzomib) that has also shown no need for dose adjustment in MM patients with RI.[102] Elotuzumab is a humanized immunostimulatory monoclonal IgG1 antibody that has as its target the signaling lymphocyte activation molecule F7 and is approved for use in patients with RRMM in combination with lenalidomide or pomalidomide. Besides the need for lenalidomide dose adjustment in these regimens, elotuzumab safety profile is not affected by RI.[103] Belantamab mafodotin is a first-in-class anti-B-cell maturation antigen (BCMA) immunoconjugate with a humanized IgG1 anti-BCMA MoAb conjugated by a maleimidocaproyl linker to a microtubule-disrupting agent, monomethyl auristatin F. This is being used in a limited fashion with recent withdrawal from the US market. Its single-agent anti-MM activity is not influenced by mild-to-moderate RI, but no data are available for severe RI and clinical trials are underway.[104] Teclistamab is a bispecific BCMA-directed CD3 T-cell engager, which binds BCMA on plasma cells and CD3 on T lymphocyte with the activation of T-cell receptor and resultant tumoricidal activity. There is no indication to reduce the scheduled dose of 1.5 mg/kg weekly of teclistamab by renal function, but prospective confirmatory data are needed.[105] Finally, engineered T cells against BCMA on MM cells (CAR-T) have been a landmark addition to management options for

MM, aiming to provide deep responses and long treatment-free intervals in patients. Similar to other novel immunotherapies, anti-BCMA CAR-T cells have not been reported to have any detrimental effects in patients with RI, although prospective studies establishing their safety and efficacy in MM patients with varying degrees of RI are not yet available.[106] A summary of various strategies in managing MM patients with RI is presented in Figure 2.

CONCLUSION

Lack of universal representation of patients in prospective data generation has led to creation of underrepresented groups in the MM demographic. Although all patients have universally benefitted from a wide range of therapeutic advances in MM, this benefit has been to a disparate extent, with lesser access and benefit realized for some of these traditionally underrepresented groups. Increased awareness of these issues, addressing any implicit or explicit bias, universal inclusion in prospective clinical trials, and day-to-day acknowledgment of these clinical and sociodemographic factors will help in achieving an efficient patient-physician partnership and achieve shared decision making with widespread applicability of evidence-based treatment approaches.

COVID-19 and Other Viral Infections in Patients With Hematologic Malignancies

Courtney E. Harris, MD[1]; Abi Vijenthira, MD[2,3]; Shin Yeu Ong, MD[4,5]; Lindsey Robert Baden, MD[1]; Lisa K. Hicks, MSc, MD[2,6]; and John H. Baird, MD[5]

Overview

COVID-19 and our armamentarium of strategies to combat it have evolved dramatically since the virus first emerged in late 2019. Vaccination remains the primary strategy to prevent severe illness, although the protective effect can vary in patients with hematologic malignancy. Strategies such as additional vaccine doses and now bivalent boosters can contribute to increased immune response, especially in the face of evolving viral variants. Because of these new variants, no approved monoclonal antibodies are available for pre-exposure or postexposure prophylaxis. Patients with symptomatic, mild-to-moderate COVID-19 and risk features for developing severe COVID-19, who present within 5-7 days of symptom onset, should be offered outpatient therapy with nirmatrelvir/ritonavir (NR) or in some cases with intravenous (IV) remdesivir. NR interacts with many blood cancer treatments, and reviewing drug interactions is essential. Patients with severe COVID-19 should be managed with IV remdesivir, tocilizumab (or an alternate interleukin-6 receptor blocker), or baricitinib, as indicated based on the severity of illness. Dexamethasone can be considered on an individual basis, weighing oxygen requirements and patients' underlying disease and their perceived ability to clear infection. Finally, as CD19-targeted and B-cell maturation (BCMA)–targeted chimeric antigen receptor (CAR) T-cell therapies become more heavily used for relapsed/refractory hematologic malignancies, viral infections including COVID-19 are increasingly recognized as common complications, but data on risk factors and prophylaxis in this patient population are scarce. We summarize the available evidence regarding viral infections after CAR T-cell therapy.

INTRODUCTION

The COVID-19 pandemic has caused significant morbidity and mortality worldwide, disproportionately affecting patients with impaired immune function, such as those with underlying hematologic or oncologic disease or because of active cancer therapy. Vaccines have emerged as one of the most powerful tools for preventing COVID-19 illness and its complications. The efficacy of vaccination in this patient population, however, can vary. This section summarizes the evidence for COVID-19 prevention with vaccines (including bivalent boosters) and monoclonal antibodies (mAbs) in oncology patients.

COVID-19 INITIAL (MONOVALENT) VACCINES

The pandemic has not only upended the medical community in many ways but has also led to significant advances in vaccine development. With billions of COVID-19 vaccine doses administered worldwide, the safety and efficacy of these vaccines in preventing severe disease and death have been demonstrated. As of December 2022, there were 242 vaccine candidates worldwide, with 50 approved for use with a variety of immunogens used. The prefusion-stabilized spike protein of the SARS-CoV-2[1] is the most used vaccine antigen. This review will focus primarily on vaccinations currently approved in the United States (Table 1). The three types of vaccines approved or authorized in the United States include nucleic acid, protein subunit, and viral vector delivery systems. Nucleic acid (messenger RNA or mRNA) and viral vector vaccines use cellular processes to make the conformationally appropriate protein (spike) to elicit a protective immune response while protein subunit vaccines deliver the immunogen directly.

Of the four vaccines approved in the United States, two use mRNA technology. Pfizer-BioNTech's Comirnaty (BNT162b2) was approved by the US Food and Drug Administration (FDA) in August 2021 for individuals age 16 years and older after receiving FDA Emergency Use Authorization (EUA) in December 2020 after demonstrating efficacy at preventing mild-to-moderate COVID-19.[2] BNT162b2 is currently approved for individuals age 12 years and older for a primary series of two doses separated by 3-8 weeks and for age 6 months to 11 years under EUA, with trials assessing a primary series of three vaccine doses.[3]

Moderna's Spikevax (mRNA-1273) is the second mRNA vaccine also granted EUA in December 2020

PRACTICAL APPLICATIONS

- Patients with blood cancer are at elevated risk of morbidity and mortality from COVID-19.
- Vaccination remains the most important line of defense against COVID-19, including among patients with blood cancer.
- Outpatient and inpatient evidence-based treatments are available to decrease the morbidity and mortality of COVID-19 among patients with blood cancer.
- Viral infections, especially respiratory viruses, are prevalent in the later phase after chimeric antigen receptor (CAR) T-cell therapy, when lymphopenia and hypogammaglobulinemia become common.
- Mortality after COVID-19 infection in CAR T-cell recipients remains high, and prevention with adequate mask wearing and social distancing and repeated booster doses of mRNA vaccines to maximize T-cell response are part of ongoing consensus recommendations.

and full approval for individuals age 18 years and older in January 2022. The primary series has two doses 4 weeks apart for all age groups, with a vaccine efficacy of 94% to prevent mild-to-moderate COVID infection.[4] The CDC recommends that males age 12-39 years receiving the second dose of the primary series can consider increasing duration until 8 weeks after the first dose to minimize the risk of myocarditis.[5] Myocarditis is reported as a complication in both mRNA vaccines, more common in males, those younger than 30 years, and after the second dose of the vaccines.[6,7] Limitations in mRNA vaccines include the need for storage at freezer temperatures, which can, unfortunately, constrain access or hinder distribution in some settings. Dosages for children are different than those for adults, which will not be covered here in detail.

The third approved vaccine is Johnson & Johnson's Janssen (Ad26.COV2.S) virus vector vaccine, a replication-incompetent adenovirus 26 vector, which was authorized in February 2021. The initial one-shot strategy led to ease of administration and uptake; however, vaccine efficacy against severe critical disease was lower (85%),[8] and several months after EUA, concerns about reports of severe cerebral venous sinus thrombosis related to vaccine-induced antiplatelet factor-4 antibodies prompted a pause on the vaccine (which was eventually lifted).[9] However, in December 2021, the CDC recommended a preference for mRNA vaccinations. Ultimately, guidance on use emerged stating that the vaccine is available for adults 18 years and older who request the vaccine or have a contraindication to other vaccination types and should not be given to persons with a history of thrombosis with thrombocytopenia or heparin-induced thrombocytopenia.

The fourth vaccine created by Novavax (Nuvaxovid and Covovax NVX-CoV2373) is a recombinant, protein-adjuvanted vaccine that in studies has performed similarly to mRNA vaccines (90% efficacy in clinical trials[10,11]) and was the fourth COVID-19 vaccination to receive EUA in the United States in July 2022 for individuals age 12 years and older, two doses 3-8 weeks apart.

The speed with which these vaccines emerged partly relates to different manufacturing processes, with the mRNA platform being the nimblest. The challenges in manufacturing are a significant consideration as public health authorities plan future updates to these vaccines and determine the clinical importance of the vaccine insert/antigen matching the circulating stain as closely as possible, an issue the community routinely debates with the annual influenza vaccine.

VACCINE RESPONSE IN IMMUNOCOMPROMISED HOSTS AND ADDITIONAL VACCINE DOSES

Because of many studies demonstrating lower vaccine effectiveness and decreased or absent neutralizing antibody response in patients with underlying hematologic malignancy or receiving B-cell depleting therapies,[12-15] the Advisory Committee on Immunization Practices advised immunocompromised patients who received mRNA vaccination two-dose series to receive a third mRNA vaccine dose as part of their primary series 4 weeks after the second dose or a first dose of mRNA vaccine if Ad26.COV2.S was

TABLE 1. Approved/Authorized SARS-CoV-2 Vaccines in the United States

Name of Vaccine	Date EUA Issued for Primary Series in Adults	Date of FDA Approval	Delivery System
Pfizer-BioNTech Comirnaty BNT162b2[92]	December 11, 2020	August 23, 2021	mRNA

given previously.[16] Patients are considered immunocompromised with the use of active chemotherapy, hematologic malignancy, hematopoietic stem-cell or solid organ transplant (SOT), untreated HIV with CD <200, moderate-to-severe primary immunodeficiency, or immunosuppressive therapy (including but not limited to the use of rituximab, steroid equivalent of prednisone >20 mg/day once daily for >14 days).[17] Those with hematologic malignancy, specifically those receiving anti-CD20 agents, often fail to develop neutralizing antibodies to COVID-19 and are at high risk for COVID-19–associated complications.[18,19] In these patients, the emergence of COVID-19–specific T-cell responses is associated with clinical improvement, pointing out the importance of redundancy in adaptive immune responses.[19] Given the many logistical challenges in assessing T-cell responses, many immunologic assessments of vaccine-elicited immune responses have focused on neutralizing and binding antibodies. In other immunosuppressed populations, such as those who have received a SOT, observational studies have demonstrated higher immune responses and vaccine efficacy with a three-dose mRNA initial series compared with two doses.[20-23]

Other strategies to consider improving immune responses to vaccination include holding immunosuppression around the timing of vaccination or strategically timing vaccination to target periods of lower immunosuppression or breaks in therapy (eg, 4 weeks before rituximab administration[24] and in SOT, decreasing mycophenolate mofetil dosing at the time of vaccination[25]). Finally, revaccination with primary series should be considered for any individual 3 months after undergoing hematopoietic stem-cell transplantation or chimeric antigen receptor (CAR) T-cell therapy.[26]

BOOSTERS (MONOVALENT AND BIVALENT)

Waning of immune responses associated with increased breakthrough infections has been observed after the completion of the primary vaccination series.[27,28] This led to broad recommendations for vaccine booster immunizations in the late summer of 2021. Subsequent work has raised questions about the frequency of booster immunizations, given an improved understanding of the durability of protection. It is important to carefully assess the significance of breakthrough infections as these are mainly mild-to-moderate illnesses with persistent strong protection against severe illness and death.

Another important consideration is the viral evolution that has occurred, allowing the virus to better adapt to the human host and transmit more efficiently, as well as to escape dominant immune responses. With new emerging variants that can escape previous immune responses, such as the Omicron variants, rapid global spread occurs. The emergence of new variants, which can partially escape previous immunity, raises important considerations for vaccine development and which vaccine antigen(s) should be in the vaccines used.

For example, the emergence of the Omicron variants and concern for decreased efficacy of the original vaccine antigens in use led the FDA on August 31, 2022, to provide EUA for the bivalent mRNA vaccine boosters (Pfizer bivalent if 5 years and older and Moderna 6 months and older) that target the Omicron BA.4/5 variants and deauthorize the original monovalent vaccine antigen. This decision was based mainly on immunologic data demonstrating improved Omicron-directed neutralizing antibody immune responses and dominance of the Omicron variants circulating in the community. Notably, other communities, such as the United Kingdom, authorized the BA.1 component rather than BA.4/5.

These vaccines contain equal parts of the spike protein sequence from the initial ancestral strain and BA.4/5 strains of the Omicron variant (B.1.1.529). They can be administered 2 months after completing the primary series or monovalent boosters from any of the four vaccine regimens listed above (only mRNA boosters are currently available).[29] Since approval, bivalent boosters have been shown to provide additional protection against severe infection during Omicron waves that emerged in late 2021, even in those previously vaccinated and boosted, with vaccine effectiveness similar to mRNA vaccines and conferring an increase in Omicron-neutralizing antibodies.[30,31] Furthermore, bivalent mRNA boosters have demonstrated protection in the immunocompetent against symptomatic disease for at least 3 months in the fight against ever-evolving variants, most recently, Omicron BA.2-related sublineage XBB.1.5, which emerged in early 2023, although overall low population uptake of bivalent boosters has been noted (approximately 10% of the eligible population).[32] It remains difficult to tease out the importance of the vaccine antigen matching the circulating strains versus the waning of immunity over time as to the drivers of booster-associated protection. Efficacy data on these strategies should be forthcoming.[33]

The impact of waning immunity and long-standing vaccination strategies are not yet known. In the future, it will be important to weigh the goals of achieving high serum-neutralizing antibody levels and long-standing cellular immunity against booster fatigue and the need for clear, consistent communication. Future recommendations regarding booster doses will require robust supporting evidence to achieve what we define as success (eg, preventing hospitalizations and death).[34,35]

MONOCLONAL ANTIBODIES FOR PREVENTION OF DISEASE IN ONCOLOGY PATIENTS

mAbs have been demonstrated to have a role in preventing COVID-19 infection in patients at high risk of severe disease

as either pre-exposure or postexposure prophylaxis (such as those with household contacts who are infected with COVID-19). mAbs function as passive immunity as an antibody cocktail containing different antibodies targeting the spike protein, such as the receptor-binding domain. Given the risk of viral escape, using two antibodies can minimize the mutational escape of the virus and prolong the utility of a given mAb cocktail. During the pandemic, availability, cost, and logistics of outpatient administration of mAbs were barriers to widespread use; however, the emergence of escape mutants is an even larger barrier to these therapies. Intramuscular AZD7442 (tixagevimab and cilgavimab—Evusheld), a combined mAb, was authorized for EUA in December 2021[36] after the initial study showed a relative risk reduction of symptomatic COVID-19 of 83% at 6 months in those who had an inadequate vaccine response.[37] Further studies confirmed this protective effect[38,39] and showed increased protection with higher doses, adjusted in guidance.[40] This was the only mAb approved for pre-exposure prophylaxis until January 23, 2023, when the FDA revised the EUA to limit use, as the new nonsusceptible Omicron subvariants (XBB.1.5, BQ.1.1) were projected to be more than 90% of infections in the United States.[41] As such, there are currently no approved mAbs for pre-exposure prophylaxis.

Postexposure prophylaxis, like pre-exposure prophylaxis, was previously authorized by EUA by the FDA for mAb casirivimab-imdevimab (REGEN-COV)[42] and bamlanivimab-etesevimab[43] to prevent SARS-CoV-2 infection in select individuals older than 12 years. Casirivimab-imdevimab decreased the risk of developing symptomatic and asymptomatic infection and reduced the duration of symptoms and high viral load in household contacts.[44] Bamlanivimab alone was assessed in nursing home residents to reduce the risk of developing COVID-19.[45] Although these therapies were effective during surges of cases with delta variants, with the onset of the Omicron subvariants, both treatments are rendered ineffective and thus are no longer supported by EUA. No current mAb therapies are currently available for clinical use for circulating variants.

In addition to vaccination strategies, it is essential to implement other measures to reduce the risk of COVID-19 in oncology patients. These measures include social distancing, mask wearing, and hand hygiene. Oncology clinics may also consider implementing telemedicine and other virtual care options to reduce the risk of exposure to the SARS-CoV-2 virus in the clinical setting. All household members should also be vaccinated to enhance the cocooning of vulnerable patients. Ultimately, a multifaceted approach that includes vaccination, nonpharmacologic interventions, and close monitoring of oncology patients is necessary to prevent and manage COVID-19 in this vulnerable population.

COVID-19 MANAGEMENT IN PATIENTS WITH HEMATOLOGIC MALIGNANCIES

Vaccination is the most important tool to decrease morbidity and mortality from COVID-19, but not all patients accept or have access to complete vaccination. Additionally, as discussed above, some patients with blood cancer remain at risk of severe COVID-19 despite being fully vaccinated.

This section reviews the management of adult patients with blood cancer and COVID-19, focusing on outpatient management and implications for ongoing cancer treatment. The COVID-19 field continues to evolve rapidly, and review articles are at risk of needing to be updated soon after publication. Fortunately, high-quality, evidence-based guidelines, including three living guidelines, are available on this topic (Table 2).

OUTPATIENT MANAGEMENT

Severe COVID-19 is defined as SARS-CoV-2 infection with hypoxemia, respiratory distress (respiratory rate >30), and/or severe pneumonia on imaging (>50% infiltrates).[46,47] Patients with mild-to-moderate COVID-19, who are at high risk of progression to severe COVID-19, should be

TABLE 3. When to Consider Antiviral Treatment in Patients With Active or Previous Blood Cancer and Symptomatic, Mild-to-Moderate COVID-19

COVID-19 Treatment Recommended[a]	Reasonable to Consider COVID-19 Treatment[a]	May Not Need Treatment for COVID-19
Age older than 65 years Unvaccinated Partially vaccinated and/or last shot >6 months prior Vaccinated, but anticipate poor response to vaccination because of immunodeficiency, past administration of B-cell–depleting therapy, hypogammaglobulinemia, etc On active treatment for blood cancer Within 2 years of stem-cell transplant or CAR-T therapy Solid organ transplant HIV with CD4 count <200 ≥1 additional comorbidity on CDC list[49] Living in long-term care	Absence of risk factors in column 1 and age 50-64 years	None of the risk factors in column 1 or 2 and able to follow-up in the event of clinical deterioration

NOTE. This table considers inclusion criteria of relevant randomized clinical trials, CDC systematic review of risk factors, and National Institutes of Health guidelines.[46,49-52,59] Decisions to treat should be made using a shared decision-making framework.
Abbreviations: CAR, chimeric antigen receptor; CDC, Centers for Disease Control and Prevention.
[a]COVID-19 treatment should only be offered in the absence of known contraindications to treatment.

considered for outpatient, antiviral treatment.[46-48] Table 3 outlines an approach to risk stratification in patients with hematologic malignancy informed by National Institutes of Health guidance, CDC risk criteria, and inclusion criteria from relevant trials.[49-52] The most important and consistently identified risk factor of severe COVID-19 is older age. An active or recent diagnosis of blood cancer, cancer treatment (especially B-cell–depleting treatments), immunodeficiency, transplant (cellular or solid organ), cellular therapy, >1 major comorbidity, and absent, incomplete, or distant (>6 months prior) vaccination are all associated with a higher risk of severe COVID. It is anticipated that most patients followed in blood cancer clinics will have risk features for severe COVID-19.

Figure 1 illustrates a pragmatic, evidence-based approach to outpatient management of adult patients with blood cancer and symptomatic, mild-to-moderate COVID-19. In the absence of contraindications, nonhypoxemic patients with risk features for progression to severe COVID-19 should be offered antiviral therapy if presenting within 5-7 days of symptom onset. All patients with blood cancer and mild-to-moderate COVID-19 should receive supportive care and be counseled regarding symptoms that should trigger an urgent reassessment. Where available, telehealth-based COVID-19 monitoring clinics can be helpful.

At the time of writing, the recommended first-line treatment for symptomatic, higher-risk outpatients with mild-to-moderate COVID-19, presenting within 5 days of symptom onset, is nirmatrelvir plus ritonavir (NR).[46,47] NR received emergency use authorization from the FDA in December 2021 after the EPIC-HR clinical trial showed that among unvaccinated patients, without a known history of COVID-19, presenting for treatment within 5 days of symptom onset, a 5-day course of NR reduced the 28-day rate of COVID-19 hospitalization, and/or death from COVID-19 from 6.3% to 0.77% with a number needed to treat (NNT) of 18.[50] Although prospective data are lacking in a vaccinated/naturally immune population, large real-world observational studies suggest that NR remains beneficial in this setting, reducing the risk of hospitalization or death, albeit with a higher NNT.[53-55] A large, ongoing UK randomized clinical trial (RCT) is expected to shed further light on the efficacy of NR in a vaccinated population.[52]

Importantly, patients with severe renal or hepatic dysfunction are not eligible for NR. Ritonavir (R) is also an inhibitor of CYP3A4, and drug interactions can complicate or prevent its use. Many treatments for hematologic malignancy have important interactions with R (eg, BTK inhibitors, tyrosine kinase inhibitors, and venetoclax). Clinicians should consult their local pharmacist regarding potential interactions and/or access available drug interaction databases such as the Liverpool Drug Interaction Database[56] or the University Health Network online reference on NR drug interactions in oncology.[57]

Intravenous (IV) remdesivir represents an alternative to NR in eligible patients presenting within 7 days of symptom onset. In an RCT of nonhypoxemic, unvaccinated, higher-risk outpatients, remdesivir reduced the risk of hospitalization or death within 28 days from 5.3% to 0.7% with an NNT of 22.[51] A small number of patients in this trial had immune compromise and/or cancer (4.1% and 5.3%, respectively). As with NR, prospective data on the efficacy of remdesivir in a vaccinated and/or naturally immune population are lacking, and the NNT is likely higher in this context. Like NR, remdesivir is not recommended in patients with a creatinine clearance of <30 mL/min, although some experts suggest that it can be used with caution and close monitoring. However, the main barrier to remdesivir is

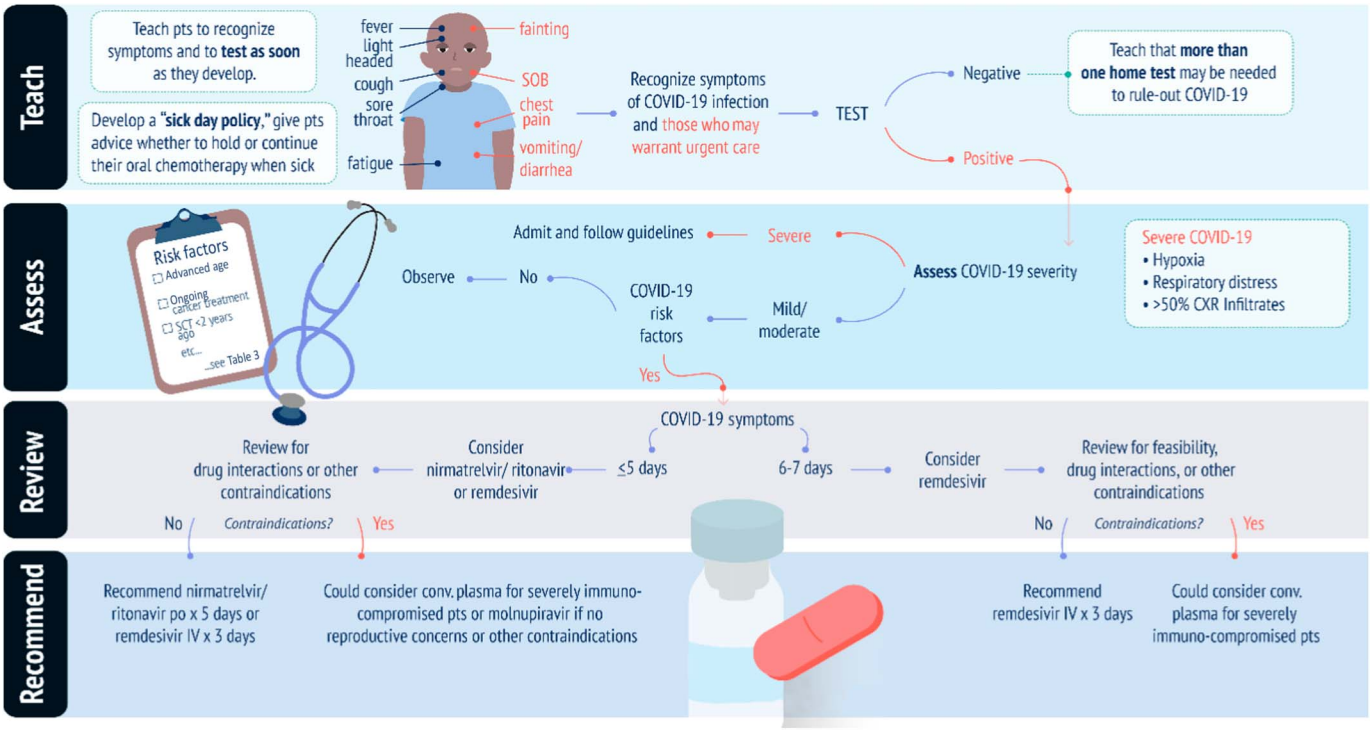

FIG 1. Approach to outpatient management of patients with blood cancer and COVID-19. conv., convalescent; CXR, chest x-ray; IV, intravenously; po, orally; pts, patients; SCT, stem-cell transplant; SOB, shortness of breath.

operational. The drug requires three consecutive days of IV administration started within 7 days of symptom onset—a challenge for many clinics which operate 5 days a week and may not have the capacity to safely isolate patients with COVID-19 from other immunocompromised patients with cancer.

When neither NR nor remdesivir is available nor appropriate, some guidelines[46,48] recommend molnupiravir. The MOVe-OUT study reported that among higher risk, outpatients with mild-to-moderate COVID-19, presenting within 5 days of symptom onset, hospitalization/death within 29 days decreased from 9.7% to 6.8% (NNT of 34) with a 5-day course of oral molnupiravir.[58] Vaccinated patients were excluded from this trial; 74.1% of included patients had no evidence of past infection, and only 2% of participants had cancer. In addition, a recent large RCT of molnupiravir in higher-risk, vaccinated patients showed limited benefit with hospitalization rate and/or death of 1% in both arms.[59] Additionally, there is concern about the mutagenic potential of this drug.[48] Nonetheless, it remains an option for selected high-risk outpatients with blood cancer who have contraindications to NR and remdesivir.

As previously discussed, mAbs were recommended for the outpatient treatment of COVID-19; however, in vitro data show that these agents are not effective against newly dominant SARS-CoV-2 variants, and thus, they are no longer recommended.[46,48] There are some data suggesting benefit from high-titer convalescent plasma, among immunocompromised outpatients, particularly those without an effective response to vaccination. However, data are mixed[48] and operational challenges limit this therapy's routine use, even in resource-rich environments.

Emerging outpatient therapies for COVID-19 are not yet approved for clinical use but may become available in the coming months and years. Oral analogs of remdesivir are under active investigation, and a recent RCT reported that VV116 (one such analog) is noninferior to NR in reducing symptoms among patients with mild-to-moderate COVID-19.[60] mAbs targeting regions of the SARS-CoV-2 virus that tend to be highly conserved are also under investigation.[61] In addition, a single subcutaneous injection of pegylated interferon (IFN) lambda was recently reported to reduce hospitalizations/emergency department visits, when given within 7 days of symptom onset.[62] This trial contained mostly higher-risk patients, patients infected with the Omicron variant (40%), and vaccinated patients (83% were at least partially vaccinated). Viral evolution is unlikely to overcome IFN's mechanism of action. However, data will be required among immunosuppressed patients, such as those with blood cancer, as the hepatitis C literature suggests that some immunocompromised patients are less responsive to IFN.[63]

INPATIENT MANAGEMENT

Patients who have mild-to-moderate COVID-19 and are hospitalized for other reasons should be managed in the same manner as outpatients with mild-to-moderate COVID-19. Excellent evidence-based guidelines are available regarding the management of patients with severe COVID-19 (Table 2), and a detailed discussion of the evidence is outside of the scope of this review. Briefly, a 5-day course of IV remdesivir is recommended in patients who require conventional oxygen support, but not among those requiring high-flow oxygen or mechanical ventilation. A 10-day course of low-dose (6 mg daily) dexamethasone is generally recommended in patients with hypoxemia; the course can be shortened in those ready for early discharge. Notably, patients with blood cancers were not represented in trials of dexamethasone in moderate-to-severe COVID-19,[64,65] and potential benefits need to be weighed against the risks of additional immunosuppression in this vulnerable population. In patients with critical COVID-19, evidence supports the addition of tocilizumab (or an alternate interleukin-6 receptor blocker) or baricitinib (a JAK inhibitor).[46-48]

Therapeutic anticoagulation is recommended for nonpregnant hospitalized patients who require oxygen and have D-dimer levels above the upper limit of normal in the absence of excess bleeding risk.[46] All other patients should receive prophylactic anticoagulation. The recommendation for therapeutic anticoagulation is based on three randomized controlled trials that demonstrated improvements in mortality as a secondary outcome, thrombosis and/or mortality as a composite outcome, or organ-support free days.[66-68] These trials included <10% patients with cancer. Special considerations in patients with hematologic malignancy include the possibility of thrombocytopenia, increased risk of thrombosis, and increased risk of bleeding with therapeutic anticoagulation compared with other patients.

APPROACH TO CANCER TREATMENTS

In most cases, holding immunosuppressive cancer therapy in patients with acute COVID-19 infection is appropriate. However, it is acknowledged that with some aggressive blood cancers, there can be competing causes of morbidity and mortality and that in some situations, cancer treatment may take precedence. When deciding to hold versus continue cancer treatment, clinicians should consider factors such as the urgency of cancer treatment, the intention of treatment (curative versus palliative), the anticipated depth of immunosuppression, the severity of COVID-19 symptoms, and the patient's risk of progressing to severe COVID-19. Decisions regarding when to resume cancer treatment depend on symptom resolution, local infection control practices, and the urgency of cancer treatment. In some cases, polymerase chain reaction (PCR) cycle threshold values (the number of PCR cycles required to reach threshold of positivity) and chest imaging may help the clinician distinguish between active COVID-19 infection and a residual positive test from resolved infection. Workup should be undertaken to assess for persistent COVID-19 infection, opportunistic infection or coinfection, and/or complications of COVID-19 in those with ongoing symptoms. Patients with suspected persistent infection should be discussed with local infectious disease experts.

VIRAL INFECTIONS AFTER CAR T-CELL THERAPIES

Patients receiving CD19- or BCMA-directed CAR T cells are at increased risk of infectious complications because of a combination of effects related to previous and concurrent therapies. On-target effects of the lymphodepletion (LD) chemotherapy and adoptive T cells include the depletion of B cells and plasma cells, leading to selective aplasia and subsequent hypogammaglobulinemia, loss of the endogenous helper T-cell repertoire, and reduced ability to mount an adaptive response to viral infections.[69] Interventions to mitigate CAR T-cell–associated toxicities, including treatment of cytokine release syndrome (CRS) and immune effector cell–associated neurotoxicity syndrome (ICANS) with corticosteroids and tocilizumab, also contribute to immune dysregulation and an increased risk of infection. Furthermore, all currently available commercial CAR T-cell therapies for B-cell non-Hodgkin lymphoma (B-NHL) or multiple myeloma are approved for patients with multiply relapsed or refractory disease, with patients' previous treatments further contributing to baseline depleted antibody repertoire and reduced ability to mount viral-specific neutralizing antibodies.[69] The CAR construct has an indirect impact on infectious risk—CD28-based constructs confer a higher risk of severe CRS and ICANS that often require greater dose intensity of steroids and/or anticytokine therapies to manage compared with 4-1BB–based constructs; BCMA-directed constructs produce a more profound B-cell and plasma cell depletion, leading to greater degrees of hypogammaglobulinemia and loss of viral-specific humoral repertoire.[70] In a retrospective single-institutional study of infectious outcomes after anti-BCMA and anti-CD19 CAR T-cell therapies, the incidence of viral infections in the first year was much higher in patients receiving anti-BCMA CAR T cells (53% *v* 20%, respectively).[71]

EPIDEMIOLOGY AND RISK FACTORS FOR VIRAL INFECTIONS POST-CAR T-CELL INFUSION

Data on infectious complications following after T-cell therapy have been derived primarily from single-center retrospective studies and scant adverse event reporting provided from registry trials and are difficult to interpret because of the wide variability in patient characteristics and center-specific antimicrobial and antiviral prophylaxis use. In contrast to bacterial pathogens that predominate early

when neutropenia is most prevalent (often designated within the first 30 days postinfusion), viruses are more prevalent after day +30 when lymphopenia and hypogammaglobulinemia become two critical components of immune dysfunction.[72] The cumulative incidence of viral infections in patients undergoing CD19 and BCMA CAR T-cell therapies over the first year postinfusion ranges from 8.3% to 28% and 28% to 53%, respectively (Table 4).

Risk factors for viral infections identified in multivariate analyses include previous autologous or allogeneic stem-cell transplant, receipt of bridging therapy, and receipt of steroids or tocilizumab postinfusion.[73] Prolonged CD4 T-cell lymphopenia, B-cell aplasia, and hypogammaglobulinemia affect up to 46% of patients at day +90 and have variably been associated with increased infection density.[74,75] Opportunistic viral respiratory pathogens appear to be the most common late infection after CAR T-cell infusion, with rhinovirus being the most common pathogen identified.[69,75,76] This may be related to CAR T-cell recipients transitioning back to the community early after treatment. Less common infections include herpes simplex virus (HSV) and varicella zoster virus (VZV) reactivation, given the near universal prophylaxis with acyclovir, but have been described in association with stomatitis, cutaneous eruptions, encephalitis, hepatitis, esophagitis, pneumonitis, or bone marrow suppression.[69,75,76] Human herpesvirus 6 reactivation has been associated with encephalitis, bone marrow suppression, and pneumonitis in case reports.[74,77] Although data are limited, symptomatic cytomegalovirus reactivation appears to be uncommon while asymptomatic viremia may be more prevalent than previously recognized.[75,78] Routine monitoring is not currently advised, except in high-risk patients (eg, after allogeneic transplant or `exposure to high-dose/long-term corticosteroids). Progressive multifocal leukoencephalopathy due to JC virus has been reported in a patient with relapsed large B-cell lymphoma 1 year after CAR T-cell therapy.[79] Finally, CAR T-cell manufacturing and subsequent treatment are feasible and safe in patients with hepatitis B virus (HBV),[80,81] hepatitis C virus,[82] and HIV[83,84] infections, provided adequate treatment leads to undetectable viral loads before apheresis and starting LD.[85] A cohort of 70 patients identified as chronic HBV carriers before receiving CAR T-cell therapy demonstrated no significant difference in toxicity and response when compared with patients without HBV.[86]

COVID-19 (SARS-CoV-2) IN CAR T-CELL PATIENTS

Patients with hematologic malignancies undergoing cellular therapy are among the highest risk group of developing severe SARS-CoV-2 infection and having prolonged viral clearance time of up to 2 months.[87] Data from the European Hematology Association (EHA) reported an incidence of COVID-19 of 4.8% with a median time from CAR T-cell therapy to infection of 169 days. Severe illness was observed in 67%, and COVID-19–related mortality was around 50%, which is significantly higher compared with the case fatality ratio of 1.8% in the general US population.[88,89] Another study also reported a high mortality rate of 45% at 6 months after COVID-19 diagnosis.[90] Mortality after SARS-CoV-2 infection in CAR T-cell recipients was also higher than in stem-cell transplant recipients (approximately 32%),[91] likely because CAR T-cell recipients have on average higher comorbidity burdens. Lymphopenia was an independent factor correlating with the degree of COVID-19 severity. Prevention with adequate mask wearing, social distancing, and repeated booster doses of mRNA vaccines to maximize T-cell response is part of ongoing consensus recommendations.[26]

ANTIVIRAL PROPHYLAXIS IN CAR T-CELL PATIENTS

Primary data are lacking on the optimal regimen and duration for antimicrobial prophylaxis after CAR T-cell infusion, and thus, current guidance is based on expert opinion.[72,75] Acyclovir is recommended from the initiation of LD chemotherapy for HSV prophylaxis. The duration of acyclovir use should be for at least a year or until CD4 lymphocyte counts recover to >200 cells/μL. Patients who are hepatitis B carriers (HBs Ag–positive or detectable HBV DNA in blood) should strongly consider prophylaxis with entecavir or tenofovir for at least 6 months, along with surveillance for reactivation by checking liver function test and HBV DNA. In patients who have a history of hepatitis B infection (HBs Ag and HBV DNA–negative, anti-HBc Ab immunoglobulin G–positive), surveillance with testing for HBV DNA and liver function test every 1 -3 months can be considered as an alternative to prophylaxis. Immunoglobulin levels should be measured routinely, and IV or subcutaneous immunoglobulin replacement can be considered to maintain serum levels >400 mg/dL in adults to reduce the risk and severity of sinopulmonary infections.

Older Adults With Newly Diagnosed AML: Hot Topics for the Practicing Clinician

Catherine Lai, MD, MPH[1]; Rahul S. Bhansali, MD[1]; Eric J. Kuo, MD[2]; Gabriel Mannis, MD[2]; and Richard J. Lin, MD, PhD[3]

overview

Over the past decade, our understanding of AML pathogenesis and pathophysiology has improved significantly with mutational profiling. This has led to translational advances in therapeutic options, as there have been 10 new US Food and Drug Administration (FDA) approvals for AML therapies since 2017, half of which target specific driver mutations in *FLT3*, *IDH1*, or *IDH2*. These new agents have expanded the therapeutic armamentarium for AML, particularly for patients who are considered ineligible for intensive chemotherapy with anthracycline- and cytarabine-containing regimens. These new treatment options are relevant because the median age at diagnosis is 68 years, and outcomes for patients older than 60 years have historically been dismal. However, the optimal approach to incorporating novel agents into frontline regimens remains a clinical challenge, particularly with regard to sequencing of therapies, considering the role of allogeneic hematopoietic stem cell transplantation and managing toxicities.

INTRODUCTION

Mutational profiling has dramatically improved our understanding of AML biology, culminating in landmark updates in disease classification and risk stratification from the World Health Organization (WHO)[1] and the International Consensus Classification (ICC)[2] in 2022. Both nomenclatures remove an arbitrary 20% blast cutoff for AML diagnosis if there is a disease-defining genetic alteration, underscoring the importance of disease biology in accurate risk prognostication. The European LeukemiaNet (ELN) also updated their risk stratification[3] to specify the favorable prognostic impact of *CEBPA* bZIP domain mutations,[4-6] denote that *FLT3* internal tandem duplication (ITD) mutations are intermediate risk regardless of variant allelic frequency (VAF) or *NPM1* status,[7] and consider myelodysplasia-related genetic alterations as adverse risk.[8-13] With 10 new FDA approvals for AML therapies since 2017, the approach to frontline therapy has become substantially more nuanced as these classification changes have prompted a more personalized approach to frontline therapy and patient selection for allogeneic hematopoietic stem-cell transplantation (alloHCT). This is particularly relevant for older patients or those who are ineligible for intensive chemotherapy (IC), because their outcomes have improved only marginally over the past several decades.[14,15] Here, we discuss the emerging role of novel intensive and nonintensive combination therapies that are established or under active investigation for genetically and biologically diverse subsets of patients with AML, toxicities associated with treatment, and the role of allogeneic hematopoietic stem cell transplantation.

MIX AND MATCH: INTEGRATING BCL2, FLT3, AND IDH1/2 INHIBITORS INTO FRONTLINE ACUTE MYELOID LEUKEMIA THERAPY

Mutation-Agnostic Approach to AML

Although recent advances in AML treatment have revolved around targeting specific driver mutations, the majority of newly diagnosed patients still lack a targetable lesion in the frontline setting. Thus, optimizing a mutation-agnostic approach to treatment is critical (Fig 1A). The standard frontline approach for fit patients with AML over the past 40 years has been anthracycline- and cytarabine-containing IC.[16-18] Although IC can elicit complete remission (CR) in approximately 60%-70% of patients younger than 60-65 years,[19-24] relapse rates remain high. The addition of gemtuzumab ozogamicin, an antibody-drug conjugate targeting CD33, to traditional IC has expanded therapeutic options for patients, although the survival benefit seems limited to those with favorable-risk core binding factor AML.[25] Thus, optimizing therapies for patients with intermediate- and adverse-risk host and disease factors has been a significant focus of therapeutic development. The incorporation of venetoclax-based therapies into AML management has proven to be transformative given its synergistic activity with hypomethylating agents (HMA)—either azacitidine or decitabine[26-28]—and low-dose cytarabine (LDAC).[29-31] As venetoclax potently triggers apoptosis through BCL2 inhibition,[32] its combination with IC may also allow for an amplification of tumor cell death.[33]

PRACTICAL APPLICATIONS

- Treatment of older patients with AML involves complex decisions taking into consideration age, fitness, treatment tolerability, quality of life, and social support.
- Increased treatment options have allowed patients to live longer compared with historically dismissal outcomes.
- Integrating BCL2, FLT3, and IDH1/2 inhibitors allows for increased efficacy while minimizing toxicity compared with cytotoxic chemotherapy.
- Management of side effects of these novel agents requires personalized care for each patient.
- By improving outcomes and minimizing toxicity with incorporation of BCL2, FLT3, and IDH1/2 inhibitors, more patients may be able to proceed to allogeneic stem-cell transplant.

Venetoclax-based combinations have become the frontline standard for patients ineligible for IC. In the VIALE-A study,[26] patients with newly diagnosed AML had a median age of 76 years and were randomly assigned to receive azacitidine/venetoclax or azacitidine/placebo. The addition of venetoclax significantly improved both CR/CR with incomplete hematologic recovery (CRi) rates (66.4% *v* 28.3%) and median overall survival (OS, 14.7 months *v* 9.6 months). Furthermore, with long-term follow-up at a median of 43.2 months, patients for whom treatment achieved CR/CRi with measurable residual disease (MRD) negativity had a median OS of 34.2 months.[27] Patients in the VIALE-C study[31] also had a median age of 76 years and were randomly assigned to receive LDAC/venetoclax or LDAC/placebo with improved CR/CRi rates seen in the venetoclax group (48% *v* 13%). A 2-year follow-up from the landmark study demonstrated that the addition of venetoclax to LDAC led to a statistically significant improvement in median OS compared with LDAC/placebo (8.4 months *v* 4.1 months).[29,30] LDAC has also been studied in combination with the Hedgehog pathway inhibitor, glasdegib[34,35]; however, responses rates and OS are inferior to venetoclax-based regimens for patients ineligible for IC.

While the efficacy of venetoclax-based combinations was initially observed in those who were ineligible for IC and alloHCT, recent evidence suggests HMA/venetoclax therapy may serve as an effective bridge to alloHCT. Pollyea et al[36] found that patients older than 60 years who received azacitidine/venetoclax had a significantly improved median OS if they underwent alloHCT compared with no alloHCT (not reached [NR] *v* 17.2 months). Patients who underwent alloHCT had similar OS at 12 months whether their induction regimen consisted of azacitidine/venetoclax or IC.[37] For patients younger than 60 years, there are no prospective data demonstrating superiority of one regimen over another;

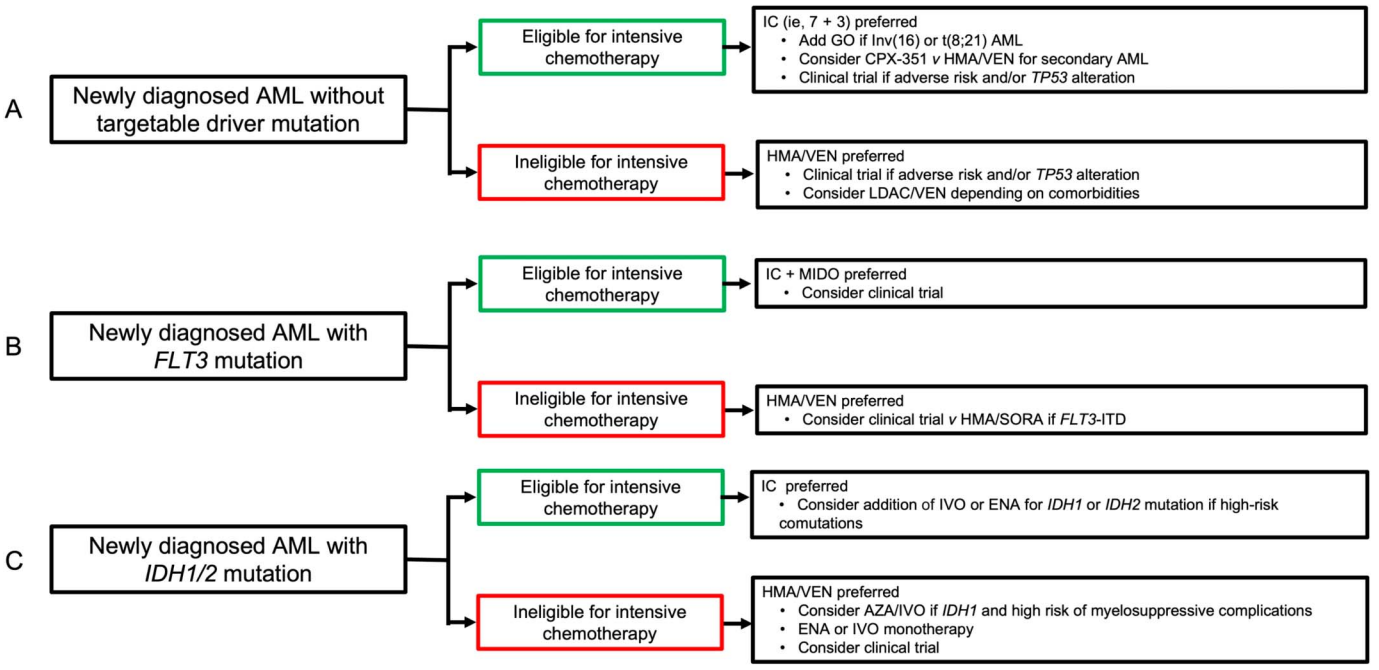

FIG 1. Approach to frontline therapy in AML. Treatment algorithm of AML induction therapy is shown. AZA, azacitidine; ENA, enasidenib; GO, gemtuzumab ozogamicin; HMA, hypomethylating agent; IC, intensive chemotherapy; ITD, internal tandem duplication; IVO, ivosidenib; LDAC, low-dose cytarabine; MIDO, midostaurin; SORA, sorafenib; VEN, venetoclax.

however, two randomized phase III studies evaluating IC versus HMA/venetoclax are ongoing (ClinicalTrials.gov identifiers: NCT04801797, NCT05177731). Retrospective data suggest that, for the overall population, there may not be significant differences in outcomes between IC and HMA/venetoclax, but selected subsets may benefit from a specific treatment strategy on the basis of mutation profile.[36-38]

Unfortunately, patients with *TP53* alterations have similarly dismal outcomes with IC or HMA/venetoclax with a 2-year survival under 15%[39] and a median OS under 6 months after alloHCT in eligible patients.[40,41] Notably, in the absence of *TP53* alterations, azacitidine/venetoclax seems to be active in patients with adverse-risk cytogenetics[42] or other high-risk mutations (ie, *ASXL1* and *RUNX1*)[38,43,44] and confers a survival benefit compared with azacitidine alone. However, several studies have demonstrated that, in the presence of *TP53* alterations, there is no significant duration of remission (DOR) or OS benefit to HMA/venetoclax compared with HMA despite significantly improved rates of CR/CRi.[26,28,42,45,46]

CD47 is a ubiquitously expressed glycosylated cell surface protein that provides an antiphagocytic don't-eat-me signal in normal cells and is overexpressed on leukemic cells promoting immune evasion.[47-49] Recent studies of the CD47 monoclonal antibody magrolimab (Hu5F9G4) demonstrate early clinical efficacy in AML harboring adverse genetic features including TP53 mutations. In a phase Ib study of patients with untreated AML and ineligible for IC,[50] treatment with azacitidine/magrolimab yielded CR/CRi rates of 56%, noting that 27% of patients had *TP53* mutations. In a phase Ib/II study of azacitidine/venetoclax/magrolimab for patients with adverse-risk AML,[51] CR/CRi rates were 63% and 86%, and 1-year OS rates were 53% and 83%, in patients with newly diagnosed AML with or without *TP53* mutations, respectively. Survival was very attenuated in patients with relapsed/refractory (R/R) AML, especially in those with previous venetoclax exposure, but a comparison of patients with *TP53* mutations treated with the magrolimab triplet versus doublet HMA/venetoclax cohorts demonstrated a significant median OS improvement (10.4 months *v* 3.5 months). Ongoing phase III studies are investigating the efficacy of azacitidine/magrolimab versus azacitidine/venetoclax or IC in patients with untreated *TP53*-mutant AML (ClinicalTrials.gov identifier: NCT04778397) as well as magrolimab/azacitidine/venetoclax versus azacitidine/venetoclax in patients with untreated AML who are ineligible for standard IC (ClinicalTrials.gov identifier: NCT05079230). Other CD47-targeting antibodies are under investigation but are not as far along in clinical development as magrolimab.

For patients considered to be candidates for IC, DiNardo et al[52] examined the efficacy of venetoclax in combination with fludarabine, cytarabine, granulocyte colony-stimulating factor (G-CSF), and idarubicin (FLAG-Ida) in a phase Ib/II study of adult patients with R/R or newly diagnosed AML. In the newly diagnosed AML arm, 29 patients with a median age of 45 years were initially enrolled, of whom 38% had adverse-risk disease. Patients received a median of two cycles of FLAG-Ida with venetoclax 400 mg once daily on days 1-14. The time to hematopoietic recovery was 31 days in the newly diagnosed AML group; aside from myelosuppression, the major toxicity of this regimen was infectious complications; nevertheless, the 30-day mortality was 0%. Ultimately, composite CR (CRc) was observed in 90% of patients with newly diagnosed AML, of whom 96% had MRD negativity. At 12-month median follow-up, the DOR was NR, and 94% of patients with newly diagnosed AML were still alive. Notably, 69% of patients with newly diagnosed AML were able to proceed to alloHCT with 24-month follow-up data demonstrating similar outcomes with median event-free survival (EFS) and OS not yet reached.[53] These findings support the feasibility of adding venetoclax to FLAG-Ida in AML in younger patients who are candidates for IC with preliminary response rates and survival surpassing those of historical cohorts and notably high rates of pretransplant MRD negativity. Although myelosuppression and infectious complications were prevalent, short-term mortality was low in this selected group of younger patients. However, caution is advised in older patients or those unfit for IC. This trial (ClinicalTrials.gov identifier: NCT03214562) is ongoing and will provide insight into future combinations with IC.

FLT3-Mutant AML

FLT3 mutations are present in 25%-32% of newly diagnosed AML cases with ITD mutations seen more frequently than tyrosine kinase domain (TKD) mutations.[54,55] Despite the development of FLT3 inhibitors (FLT3i), which have improved the outcomes for these patients, the prognostic impact of *FLT3*-ITD seems to be worse regardless of VAF or *NPM1* status. Therefore, these patients should be considered for transplant in first remission, if eligible.[56-60] Type I FLT3i are active against TKD and ITD variants while type II FLT3i are active only against ITD variants. With two FDA-approved FLT3i (midostaurin and gilteritinib) and two more in clinical development (quizartinib and crenolanib), optimizing combination therapies with FLT3i is an area of active investigation (Fig 1B).

The first approved FLT3i was midostaurin on the basis of the RATIFY trial.[61] This phase III trial randomly assigned adult patients younger than 60 years with newly diagnosed *FLT3*-mutant AML to receive midostaurin or placebo in combination with standard IC and consolidation with high-dose

cytarabine. Both groups had CR rates of 50%-60%, although the addition of midostaurin improved median EFS (8.2 months *v* 3 months) and median OS (74.7 months *v* 25.6 months). Follow-up studies observed that patients who received midostaurin had a deeper molecular remission and were more likely to ultimately receive alloHCT,[62,63] emphasizing the durable benefit in survival despite similar CR rates after induction. Moreover, another study combining midostaurin with IC in patients with newly diagnosed *FLT3*-mutant AML up to age 70 years recapitulated these findings.[64,65] CR/CRi rates after induction were similar across age groups, and most patients were able to proceed to alloHCT. The median EFS was 14.5 months and 11.7 months, and the median OS was 57.3 months and 22.7 months in the younger and older age groups, respectively. Of note, midostaurin is not approved as a single agent because of a paucity of data supporting its use for post-consolidation maintenance[60,62-64]; thus, in clinical practice, midostaurin is recommended exclusively in combination with IC and consolidation for younger patients with newly diagnosed *FLT3*-mutant AML.

While midostaurin is the only FLT3i currently recommended for frontline use in combination with IC, newer-generation, specifically targeted FLT3i are being studied in this context. Gilteritinib, which is already FDA-approved for R/R *FLT3*-mutant AML, was combined with 7 + 3 in a phase I study (ClinicalTrials.gov identifier: NCT02236013) of patients with newly diagnosed AML[66] and was noted to confer CRc rates of 81.8%. Of patients with *FLT3* mutations, the median DOR was 14.1 months, and the median OS was NR. Given these findings, two ongoing trials are studying gilteritinib versus midostaurin in addition to IC and consolidation (ClinicalTrials.gov identifiers: NCT04027309, NCT03836209). Although neither quizartinib nor crenolanib has been approved by the FDA, recent clinical trials have shown them to be effective when combined with frontline IC. Despite underwhelming results with quizartinib in R/R AML in the QuANTUM-R study,[67] the QuANTUM-FIRST study[68] suggests that it may have a role in newly diagnosed *FLT3*-ITD AML. This study enrolled patients up to age 75 years with newly diagnosed *FLT3*-ITD AML and randomly assigned them to receive quizartinib or placebo in combination with IC, consolidation, and maintenance. CR/CRi rates were slightly better in the quizartinib arm (71.6% *v* 64.9%), although DOR was significantly improved (38.6 months *v* 12.4 months), as was median OS (31.9 months *v* 15.1 months). A follow-up study also demonstrated a deeper molecular remission compared with the placebo arm[69] similar to midostaurin. If quizartinib gains FDA approval, it would add to the available agents specifically targeting *FLT3*-ITD mutations in older patients, although it does not target *FLT3*-TKD. Recent data on the use of crenolanib in combination with 7 + 3 in patients with newly diagnosed *FLT3*-mutant AML showed CR/CRi rates of at least 75%, regardless of age, ITD or TKD mutation, comutation group (except for *TP53*), *FLT3* VAF, ELN risk group, or the presence of hyperleukocytosis.[70] Moreover, MRD negativity was observed in 94% of evaluable patients, and median OS for the study population was NR at a median follow-up of 45 months. Thus, the pending data from the QuANTUM-FIRST study and ongoing trials assessing other frontline combinations with quizartinib (ClinicalTrials.gov identifiers: NCT04209725, NCT04047641), crenolanib (ClinicalTrials.gov identifier: NCT03258931), and gilteritinib (ClinicalTrials.gov identifiers: NCT04027309, NCT03836209) will potentially expand the options of FLT3i. These agents consistently seem to deepen response when combined with IC and may consequently be effective tools to improve durability of remissions, particularly if pretransplant MRD negativity can be achieved, as this has been shown to improve outcomes.[71-76]

For patients with *FLT3* mutations who are not eligible for IC, low-intensity regimens remain the standard of care. However, pooled data from VIALE-A[26] and a phase Ib HMA/venetoclax study[28] demonstrated that patients with *FLT3*-ITD had a median OS of only 9.9 months, compared with 19.2 months in those with *FLT3*-TKD despite CR/CRi rates exceeding 60% in both groups.[77] These data suggest that the efficacy of HMA/venetoclax is modest in patients with *FLT3*-ITD AML. Moreover, trials combining gilteritinib[78] or midostaurin[79] with HMA have not yielded encouraging results to date. The LACEWING trial randomly assigned patients with newly diagnosed *FLT3*-mutant AML to receive azacitidine/gilteritinib versus azacitidine alone[78]; although patients in the doublet arm had a two-fold improvement in CRc rates, the median OS was similar between both arms (9.82 months *v* 8.87 months). Despite these discouraging findings, other studies suggest synergy between FLT3i and venetoclax.[80-82] A phase II trial evaluated the use of triplet therapy (decitabine/venetoclax/FLT3i) in older patients with newly diagnosed *FLT3*-mutant AML and all adult patients with R/R *FLT3*-mutant AML. In the newly diagnosed AML cohort, the CRc rate was 92% with high rates of MRD negativity in responders. At a median follow-up of 14.5 months, median OS was NR in newly diagnosed patients (2-year OS estimated at 80%). Recent data from a trial studying azacitidine/venetoclax/gilteritinib demonstrated potency with 95% of patients with newly diagnosed AML achieving CR with an estimated 1-year OS of 80%.[83] Longer follow-up data from this study (ClinicalTrials.gov identifier: NCT04140487) and another trial investigating azacitidine/venetoclax/quizartinib (ClinicalTrials.gov identifier: NCT03661307) are pending. Thus, there may ultimately be a role for triplet FLT3i-based therapy as a lower-intensity option for patients with newly diagnosed *FLT3*-mutant AML, particularly if they have ITD.

When considering the role of FLT3i as maintenance after alloHCT, the National Comprehensive Cancer Network

(NCCN) considers sorafenib, midostaurin, and gilteritinib as options. Although frontline use of sorafenib has marginal benefit,[84,85] the SORMAIN trial[86] noted that its use as maintenance after alloHCT was associated with a 25%-30% improvement in 2-year relapse-free survival (RFS) and OS compared with placebo in patients with *FLT3*-ITD AML; these findings have since been independently corroborated.[87] An important caveat is that only nine patients in the SORMAIN trial were treated with frontline midostaurin, and none had received HMA/venetoclax.[86] Thus, while these results are certainly compelling, the gastrointestinal and skin toxicities often make long-term use challenging. Data on quizartinib for *FLT3*-ITD mutations[69] and gilteritinib seem promising, but neither is FDA-approved for this indication. A press release of the MORPHO trial (ClinicalTrials.gov identifier: NCT02997202) announced on March 9, 2023, that maintenance with gilteritinib after alloHCT for patients with *FLT3*-ITD AML did not reach primary end point of RFS over placebo,[88] although final data release is pending.

IDH1- and *IDH2*-Mutant AML

IDH1 and *IDH2* mutations are reported at a frequency of 7%-14% and 8%-19%, respectively, in AML.[89,90] Inactivating mutations in the catalytic domain of isocitrate dehydrogenase lead to buildup of the oncometabolite 2-hydroxyglutarate,[91,92] which is associated with epigenetic changes seen in AML and other malignancies.[93,94] The prognostic impact of *IDH1/2* mutations is controversial although canonically, *IDH2* mutations are thought to be relatively favorable while *IDH1* mutations confer worse outcomes.[95,96] The approval of ivosidenib, enasidenib, and olutasidenib has expanded therapeutic options for patients with R/R AML, and recent studies have been examining how to best incorporate these agents into the frontline setting (Fig 1C).

Ivosidenib or enasidenib has been studied in combination with 7 + 3 (or bioequivalent dose of idarubicin) in patients with *IDH1/IDH2* mutations throughout induction, consolidation, and maintenance.[97] The addition of either agent to 7 + 3 did not prolong count recovery and were generally well-tolerated. CRc rates in an updated report were 78.3% with ivosidenib and 73.6% with enasidenib, which are improved compared with historical controls of IC alone with these mutations.[98] Median OS was NR in the ivosidenib arm and was 25.6 months in the enasidenib arm. These data provide clinical equipoise for incorporating IDH-targeting agents into the frontline setting with IC, especially if a patient has high-risk comutations; however, in the absence of head-to-head studies, these data should be interpreted cautiously, and it should be noted that neither of these therapies are currently approved for frontline use with IC.

Both ivosidenib and enasidenib have also been studied for use as a low-intensity monotherapy for newly diagnosed AML. In studies of patients with newly diagnosed *IDH1*- or *IDH2*-mutant AML and ineligible for IC, ivosidenib[99] or enasidenib[100] monotherapy achieved CRc rates of 42.4% or 21%, respectively, with a median OS of 12.6 months or 11.3 months, respectively. Only ivosidenib is FDA-approved for frontline monotherapy use, although response rates and OS for either as single agents are modest, especially considering that patients with *IDH1/2* mutations seem to be very sensitive to azacitidine/venetoclax with outcomes similar to those achieved with IC.[101] In patients with these mutations, CR/CRi rates were reported at 79% with a median OS of 24.5 months when treated with azacitidine/venetoclax; responses and survival were comparably better with *IDH2* mutations versus *IDH1* mutations. Moreover, combinations of enasidenib and HMA in patients who are ineligible for IC have not been shown to significantly improve OS compared with HMA alone (22 months *v* 18.6 months),[102] suggesting that HMA/venetoclax should still be considered to be a first-choice low-intensity option for patients with *IDH2* mutations. For patients with *IDH1* mutations, however, the data are more compelling for azacitidine/ivosidenib as a reasonable alternative. In the AGILE study,[103] patients with newly diagnosed *IDH1*-mutant AML had significantly improved median OS when treated with azacitidine/ivosidenib compared with azacitidine alone (24 months *v* 7.9 months), leading to FDA approval of this regimen. Nevertheless, azacitidine/venetoclax should still be considered first for frontline low-intensity therapy in *IDH1*-mutant AML given comparatively improved CR rates, more familiarity with its use, and the consistent ability to bridge eligible patients to alloHCT. However, in patients who may be at high risk of myelosuppressive complications with HMA/venetoclax, azacitidine/ivosidenib is a suitable alternative. It is unknown whether responses with azacitidine/venetoclax can be improved with triplet combinations of ivosidenib or enasidenib, and increased toxicity in this older population is concerning. In an exploratory study of patients with *IDH1* mutations, patients receiving HMA/venetoclax/ivosidenib had CRc rates similar to that of venetoclax/ivosidenib, although they had a significant improvement in MRD negativity (86% *v* 25%), which was associated with a significant improvement in OS.[104] However, additional data from studies combining ivosidenib and enasidenib with azacitidine and/or venetoclax (ClinicalTrials.gov identifiers: NCT04092179, NCT03471260) will be needed to formally determine the utility of triplet regimen–incorporated *IDH1/2* inhibitors.

MANAGING THE TOXICITIES AND SUPPORTIVE CARE ASSOCIATED WITH NOVEL ACUTE MYELOID LEUKEMIA AGENTS

In 2018, the landmark VIALE-A trial led to accelerated FDA approval of venetoclax in combination with azacitidine, decitabine, or LDAC for patients with newly diagnosed AML aged at least 75 years or younger than 75 years with one of

several qualifying comorbidities (full approval occurred in 2020).[26] In relatively short order, a new standard of care was implemented across the world for the majority of patients with AML who are deemed ineligible for IC. Currently, the NCCN AML Guidelines give a category 1 recommendation for the combination of venetoclax and a HMA—either azacitidine or decitabine—as the preferred frontline regimen for IC-ineligible patients regardless of the presence of actionable mutations. The sole exception is the recent addition of the IDH1 inhibitor, ivosidenib, given in combination with azacitidine for patients with mutated *IDH1*.[105] In this section, we will focus on the practical management of patients deemed IC-ineligible who receive either venetoclax or ivosidenib in combination with HMA.

Although not the primary focus of this section, it is worth noting that the determination of fitness as it pertains to eligibility for IC is a rapidly evolving field. This determination should not be made solely on the basis of age but should incorporate an assessment of performance status, medical comorbidities, and disease biology.

HMA With Venetoclax

Starting therapy. Although administration of a HMA does not require central venous access, it is recommended for patients who require frequent lab monitoring and transfusion support before achieving remission. Previous studies have demonstrated similar toxicity profiles and efficacy of azacitidine relative to decitabine,[28] and they are likely interchangeable when used in combination with venetoclax. Peripheral intravenous (IV) administration can be considered for selected patients who have robust baseline hemoglobin and platelet counts or do not mind frequent skin pricks. Subcutaneous administration of azacitidine is another alternative; however, it is often poorly tolerated given the high prevalence of severe thrombocytopenia in patients with AML and the associated hematomas that can result from subcutaneous injections.

As the incidence of febrile neutropenia may be as high as 50% during treatment, antibacterial and antiviral prophylaxis is recommended.[106] Mold-active azole (posaconazole, voriconazole, or isavuconazole) should also be considered based on duration of previous neutropenia and regional susceptibilities to fungal infections, with appropriate venetoclax dose adjustments if azoles (or other strong CYP3A4 inhibitors) are used. Dose adjustments for concomitant azole administration[107] and other situations are shown in Table 1. Although the incidence of tumor lysis syndrome (TLS) with HMA/venetoclax in AML is low when the WBC count is not elevated,[108] adequate hydration and allopurinol prophylaxis are still routinely recommended for the first cycle of therapy but can be safely discontinued if there is no evidence of TLS and clearance of bone marrow blasts. Accordingly, inpatient hospitalization is not required for initiation of therapy but should be considered if frequent outpatient monitoring is challenging, if expedited treatment is necessary, or if the patient may be at increased risk for complications on the basis of leukocytosis (WBC >25 K/μL), impaired renal function, or other comorbid conditions. WBC count must be brought down to <25 K/μL with hydroxyurea or cytarabine before initiating therapy to minimize tumor lysis.

Common toxicities associated with this regimen include nausea, vomiting, fatigue, decreased appetite, diarrhea, and/or constipation.[26,28] Accordingly, antiemetics, antidiarrheals, and/or promotility agents are routinely prescribed on an as-needed basis on initiation of therapy.

Initiation of venetoclax includes a 3-day ramp-up. In the absence of any indications for dose adjustments, venetoclax is given as 100 mg once on day 1, 200 mg once on day 2, and 400 mg once daily on day 3 and beyond.[26]

TABLE 1. Dose Adjustments of Venetoclax on the Basis of Metabolism

Metabolic Interaction	Examples[a]	Dose Reduction (%)	New Daily Dose (mg)[b]
Strong CYP3A4 inhibitors	Clarithromycin, itraconazole, ketoconazole, voriconazole, HIV protease inhibitors	75	100
	Posaconazole	≥75	70-100
Moderate CYP3A4 inhibitor	Aprepitant, cimetidine, ciprofloxacin, cyclosporine, diltiazem, dronedarone, erythromycin, fluconazole, isavuconazole, verapamil	50	200
P-glycoprotein inhibitor	Amiodarone, carvedilol, cyclosporine, dronedarone, quinidine, ranolazine, verapamil	50	200
Strong CYP3A4 inducers	Carbamazepine, efavirenz, phenytoin, rifampin	—	Avoid use
Child-Pugh C cirrhosis		50	200
Renal impairment		None	400

[a]Examples listed are not exhaustive of all inhibitors, inducers.
[b]Dose administsered once daily.

Monitoring on treatment and restaging. The most common grade 3/4 adverse events associated with this combination include neutropenia, thrombocytopenia, and anemia. These can be especially profound in patients with antecedent hematologic malignancies or with baseline marrow hypocellularity. Accordingly, until remission is achieved, the majority of patients will require at least twice weekly monitoring of blood counts with readily available transfusion support when needed. Similarly, frequent monitoring of chemistries and uric acid should be obtained early on to monitor for TLS and other electrolyte derangements.

Unlike with HMA monotherapy, responses with the combination of HMA/venetoclax are typically achieved quickly, with a median time to response of approximately 1 month. Since the majority of patients will begin treatment with cytopenias and nearly all patients will have cytopenias by the end of the first cycle, in the absence of clear signs of persistent disease, it is essential to obtain a restaging bone marrow evaluation before cycle 2. This is performed to determine whether cytopenias are therapy-related or due to persistent disease. There is no standard for when bone marrow biopsies are performed after cycle 1 and vary by institution; this ranges from days 14 to 28. These early bone marrow biopsies help identify the significant proportion of patients in whom clearance of marrow blasts is rapid. Identifying these patients early is crucial as continuation of venetoclax without a temporary pause or a delay in the subsequent cycle may result in prolonged aplasia and a higher risk of serious infectious complications.

If patients are in CR—defined as <5% blasts—irrespective of hemoglobin or platelet count after cycle 1, it is recommended to pause venetoclax and delay initiation of the second cycle for up to 14 days or until recovery of neutropenia to less than grade 3 (ie, an absolute neutrophil count >1 K/μL). The effect of venetoclax is most pronounced on neutrophils, so normalization of platelets with persistent neutropenia is often an indicator that the neutropenia is therapy-related. If persistent disease (>5% marrow blasts) is found on the restaging biopsy, treatment should continue without delay and without a change in the venetoclax to the schedule, with plan for a repeat biopsy before the third cycle.

Management of postremission myelosuppression. Once remission is achieved, the main challenge in successfully keeping patients on continued treatment is the recurrence of grade 3/4 hematologic toxicities, most notably neutropenia. To avoid this issue, the vast majority of patients should only receive venetoclax between 14 and 21 days once remission has been achieved. If prolonged or severe cytopenias are recurrent after achieving remission, the recommendation is to decrease the number of days of venetoclax per cycle rather than change the dose of venetoclax. Although data are limited, it does not seem that a shorter duration of venetoclax postremission compromises durability of response.[109-112] Additional strategies for limiting the depth and duration of cytopenias postremission include reduction in the dose or number of days of HMA therapy and the use of supportive G-CSF for grade 3/4 neutropenia.

If cytopenias worsen at any point during the course of treatment or do not respond to dose pauses/adjustments, a repeat marrow evaluation is recommended to rule out disease progression.

HMA With Ivosidenib

Although some of the best responses to HMA/venetoclax are in patients with mutated *IDH2*, evidence suggests that those with mutated *IDH1* may respond less well.[101] Although the NCCN guidelines give a category 1 recommendation for HMA/venetoclax in patients with an IDH2 mutation, enasidenib—which targets the *IDH2* mutation—is also included as a potential monotherapy in the frontline setting on the basis of a phase I/II trial demonstrating a median OS of 11.3 months.[100] Ivosidenib monotherapy was initially approved for newly diagnosed IC-ineligible patients with mutated *IDH1* in 2019, although more recently the combination of ivosidenib and azacitidine gained approval on the basis of results from the phase III AGILE trial. In this trial, the combination of azacitidine plus ivosidenib yielded a median OS of 24 months, as compared with 7.9 months with azacitidine alone. When starting ivosidenib and azacitidine for newly diagnosed AML, management principles are similar to those that apply to starting HMA/venetoclax, including antimicrobial prophylaxis and close monitoring for hematologic, metabolic, and infectious complications. However, there is generally less myelosuppression associated with ivosidenib-based therapy. Similar to venetoclax-based therapy, dose reductions are recommended in patients receiving strong CYP34A inhibitors; ivosidenib should be reduced by 50% to a dose of 250 mg once daily in patients receiving strong CYP3A4 inhibitors. Key differences between venetoclax-based and ivosidenib-based therapy include the time-to-response assessment, the risks of QT prolongation, and differentiation syndrome (DS).

Monitoring on treatment and restaging. Prolongation of the QT interval on ECG is a known complication of ivosidenib. It is recommended to minimize the concomitant use of other QT-prolonging agents and to obtain ECGs before starting therapy, weekly for the first 3 weeks on therapy, and then monthly thereafter. For prolongation of the QTc interval >480 milliseconds, it is recommended to ensure electrolytes are repleted and to interrupt ivosidenib until the QTc returns to <480 milliseconds. Should the QTc prolong to >500 milliseconds, electrolyte repletion and interruption of ivosidenib are recommended, with subsequent reduction of

the dose from 500 mg once daily to 250 mg once daily after the QTc has returned to <480 milliseconds. This assumes there are no other culprit drugs that may be contributing to QTc prolongation that can be discontinued.

Perhaps the most notable and important-to-recognize toxicity of ivosidenib either alone or in combination with azacitidine is DS. A high index of suspicion for DS is necessary since it is commonly misdiagnosed as either disease progression or infection. In combination with azacitidine for newly diagnosed IC-ineligible patients, ivosidenib led to DS in 14% of patients, with 4% of patients experiencing DS ≥grade 3. Symptoms of DS most commonly include leukocytosis, peripheral edema, fever, dyspnea, effusions, hypotension, hypoxia, rash, and increased creatinine. In addition to hospitalization for concurrent workup of infection and disease progression, management of DS should be initiation of dexamethasone 10 mg IV or orally every 12 hours. If concomitant noninfectious leukocytosis is observed, hydroxyurea may be warranted; volume overload should be managed with diuretics. Importantly, corticosteroids and hydroxyurea should only be tapered after complete resolution of symptoms and after a minimum of 3 days. If severe symptoms of DS persist for more than 48 hours after initiation of corticosteroids, interrupt ivosidenib until signs/symptoms resolve.

Unlike venetoclax-based therapy, median time to best response with the combination of ivosidenib and azacitidine is approximately 4 months; accordingly, restaging marrow evaluations should generally occur after 3-4 cycles of azacitidine or at time of hematologic recovery. In the absence of clear signs of disease progression, it is recommended to continue ivosidenib and azacitidine for at least six cycles given the potential for late responses. When used as a single agent, ivosidenib achieved a CRc rate of 42.4% and median OS of 12.6 months.[99] Monotherapy with ivosidenib may have a lower risk of febrile neutropenia but a higher risk of diarrhea and leukocytosis. Posterior reversible encephalopathy syndrome has been reported rarely with the use of ivosidenib.

Other agents/combinations in development. There are multiple novel agents and combinations currently under study, including frontline FLT3i,[113,114] oral HMAs,[115,116] and triplets combining HMA, venetoclax, and targeted agents. At present, these are recommended only in the context of a clinical trial.

Palliative care and advanced care planning. The landscape of therapeutic options available to patients with newly diagnosed AML is rapidly evolving as many patients who choose to undergo therapy will have better outcomes than those who receive supportive care alone. Nonetheless, for all newly diagnosed IC-ineligible patients with AML, the goal of therapy remains palliative/life-prolonging rather than curative. Accordingly, we strongly recommend the early incorporation of specialty palliative care for discussion of advance care directives and for symptom management expertise. All treatment decision plans should be made in conjunction with the patient and their stated goals.

WHAT IS THE ROLE OF ALLOGENEIC STEM-CELL TRANSPLANT FOR OLDER PATIENTS WITH ACUTE MYELOID LEUKEMIA IN 2023?

Older Patients With AML: Transplant or Not?

Survival outcomes among older patients with AML remain dismal over the past several decades mainly because of the general higher disease risk, coexisting comorbidities, compromised performance status, and the inability to deliver curative intent, consolidative alloHCT to most of these patients.[117] AlloHCT is more effective over time compared with non-HCT therapies for selected older patients with AML who can achieve disease control and who have adequate level of fitness, although early treatment-related mortality should be acknowledged.[118-120] However, how to identify, expand, and optimize this population of older patients remains quite challenging without any standardization. This has become the subject of intense debate encompassing many intricate topics such as dynamic disease risks, aging biology, and the impact of treatment, long-term survival versus the early risk of death, and perhaps most importantly, patients' own perspectives on risks, quality of life, and available resources.[121-123] In fact, a recently reported, 8-year longitudinal, multicenter study of 692 older patients with AML highlighted these complexities. While alloHCT utilization was associated with a reduced risk of death, the benefit disappeared after accounting for age, comorbidity burden, disease risks, frailty, depression, and impaired function and quality of life, suggesting that alloHCT improves survival only for selected older patients who are healthier and noninfirmed.[124] Although it might be easier for clinicians to simply present all these findings and describe the population statistics, it is equally important to appreciate that each older alloHCT candidate is unique, and perspectives from all parties, including the physician, the patient, family/caregivers, and local institution, should be considered.

AlloHCT likely will continue to be an integral part of AML therapy for the foreseeable future because of its graft-versus-leukemia mechanism of action, curative potential for an older patient population which historically has the worst outcome, and, importantly, the rapidly improving transplant outcomes including older patients.[125] This notion is supported by several registry-based and prospective studies, including the most recent CIBMTR study of 1,321 older patients with AML transplanted in the contemporary era of 2007-2017. In this analysis, the 3-year OS ranged from 40% to 50%, and disease-related risk factors, rather

than increasing chronologic age, were the major determining factors for survival.[126] However, despite these findings, clinical ageism, or treatment decision on the basis of chronologic age alone, has been the most common barrier for referring older patients for consideration of alloHCT.[127] This is also supported by a recent study examining trends and factors associated with alloHCT utilization among Medicare beneficiaries with AML from 2010 to 2016. Mau et al[128] found that alloHCT utilization rate within 1 year of diagnosis had increased gradually over time from 11.9% in 2010 to 20% in 2015 and estimated that there was an unmet need of 43%-44% of older patients with AML who could benefit from alloHCT. Nevertheless, there are many reasons to believe that the future will be brighter.

Novel AML Therapies as Bridge to AlloHCT

As discussed in earlier sections of this review, AML treatments, especially for the older patient population, are rapidly expanding and evolving. These novel agents and their rational combinations are generally better tolerated than traditional intensive induction therapies such as 7 + 3 and are generally more effective, especially in combination, than the meager historical 30%-40% CR rate seen in older patients.[129] Although not considered curative, these regimens can produce high rate and high-quality remissions in older patients which potentially allow safer bridging to alloHCT. For example, older patients with AML who received induction with the novel agent CPX-351 (liposomal daunorubicin and cytarabine) and subsequently went to alloHCT had superior OS and reduced transplant-related mortality as compared with older patients who were induced with 7 + 3, followed by alloHCT.[130] This suggested that CPX-351 not only improved disease control by allowing more patients to proceed to transplant but also improved treatment tolerability and reduced subsequent nonrelapse mortality of alloHCT. Similarly, the combination of venetoclax with azacitidine could successfully bridge older patients with AML to alloHCT, resulting in superior survival compared with maintenance therapy alone in a single-institution study,[36] and single-agent ivosidenib could induce remission in older patients with AML with *IDH1* mutations, thus enabling subsequent alloHCT in otherwise ineligible candidates.[131] Finally, novel agents with significant antileukemia activity continue to emerge such as anti-CD45 Iodine (^{131}I) Apamistamab (IOMAB-B), which has been incorporated into salvage/conditioning treatment to bridge to transplant with encouraging results and is currently being evaluated for approval.[132]

Selecting the Older Candidate: Role of Geriatric Assessment

How do we select the appropriate older candidate? We need to consider disease risks, treatment response, patient preference, and findings from the comprehensive geriatric assessment (GA), which is a multidimensional, multidisciplinary, and holistic approach to evaluate an older person's functional and cognitive ability, physical mobility, mental health, and socioenvironmental circumstances to identify frailty and age-related vulnerabilities.[133] GA plays an important role in the management of older patients with AML including risk stratification at diagnosis, longitudinal (re) assessment, and potential guidance on treatment intensity and supportive care.[134,135] In the setting of alloHCT, GA has been increasingly used for pretransplant evaluation, optimization, and peritransplant management of older patients with hematologic malignancies.[136] Several common geriatric deficits including functional impairment, cognitive impairment, and polypharmacy have been shown to be associated with alloHCT outcomes including survival and treatment-related toxicities.[136] Importantly, a GA-guided, outpatient clinic-based, multidisciplinary and multifaceted, pretransplant optimization program for older patients has been shown to effectively reduce transplant-related mortality and improve survival in a pre- and poststudy design.[137] A similar pretransplant optimization program has been described at Duke University which found that 52% of patients had resolution of at least one GA deficit from the initial visit to pretransplant admission visit.[138] These findings strongly support the utility and value of GA and GA-guided, pretransplant management and optimization programs and may likely be adoptable to the post-transplant setting. Despite these advances, however, many barriers exist to fully

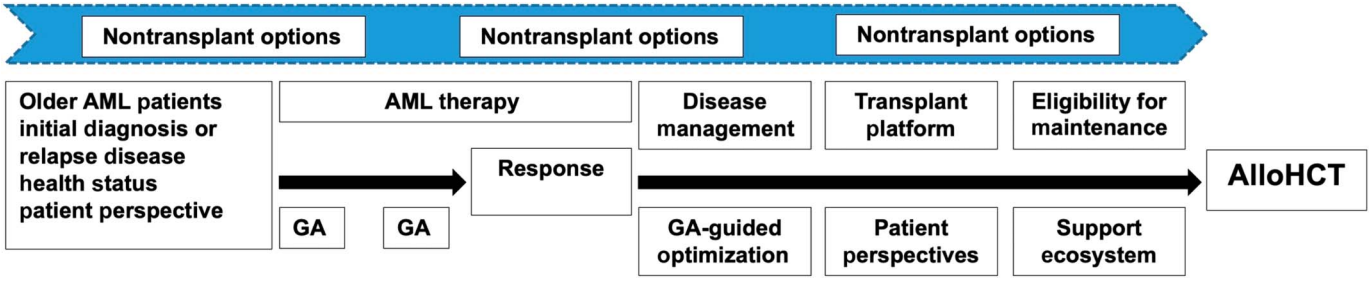

FIG 2. Integration of GA and alloHCT for older patients with AML. alloHCT, allogeneic hematopoietic stem-cell transplantation; GA, geriatric assessment.

integrate GA into transplant practices including physician perception, time constraints, staffing limitations, financial costs, and knowledge base.[139]

Expanding Horizons in AlloHCT Technology and Platforms

Importantly, the field of alloHCT is advancing steadily with improved outcomes in recent years, especially for older patients.[126,140,141] These improvements are largely attributed to the development of reduced-intensity and nonmyeloablative conditioning regimens,[142,143] advances in supportive care including newer antimicrobials such as letermovir,[144] better prophylaxis and treatment of graft-versus-host disease,[145] and more recently, increased donor choices across the human leukocyte antigen match barrier.[146] Specifically, for older patients with AML, a treosulfan-based conditioning regimen with reduced toxicity and improved antileukemia activity, as well as novel antibody-based conditioning strategies may further improve tolerability of alloHCT.[132,147] Finally, the role of maintenance therapy post-alloHCT may be of heightened importance among older patients with AML to reduce the risk of relapse, given the generally higher disease risk and lower intensity of conditioning even with MRD (MRD+) before alloHCT.[74,148] Oral agents are generally preferred given ease of administration and available evidence from the post hoc analysis of a registration trial.[149]

Integrating GA and AlloHCT Into the Total Therapy for Older Patients With AML

We are entering a new era of personalized treatments for older patients with AML with innovate, effective, and low-toxicity induction strategies; increased ability to bridge to the curative intent alloHCT for selected patients; improved donor selection and transplant platforms; and highly individualized peritransplant care to manage nononcologic geriatric issues.[150] Central to the care of older patients with AML is to incorporate early, longitudinal GA, and GA-guided management to prevent treatment-related decline[151] and to combine GA with disease risk assessment for early transplant evaluation to maximize the chance of cure for selected older patients. This likely will be a dynamic population of patients that could be expanded or preserved with appropriate GA-guided care across the treatment continuum. We propose here to incorporate GA and alloHCT as parts of total therapy for older patients with AML (Fig 2).

CONCLUSION

AML is a very complex and heterogeneous disease as evidenced by the expansion of genetic and cytogenetic qualifiers in the updated WHO and ICC classification systems. Although outcomes continue to improve on the basis of novel therapies, understanding of toxicities, and improvements in alloHCT, the long-term OS is still dismal, and we need to do better. In this regard, standardization of MRD assessment would help tailor subsequent treatment after CR and also predict relapse. Equally important is appropriate diagnostic cytogenetic, molecular, and mutational testing to understand baseline mutations and repeating this testing at relapse to understand clonal evolution. Our goal as clinicians is to optimize timing, combination, and sequence of therapy while taking physiologic age into consideration and maximizing objective measures of quality of life. This includes early assessment of GA before treatment, during treatment, and pre- and post-alloHCT. Integration of multidisciplinary services such as physical and occupational therapy, nutrition, social work, and palliative care will also insure care of the whole patient with regard to physical, social, and emotional well-being. By combining precision oncology to use the best testing with optimal treatments, we will continue to make progress in this scientifically interesting yet challenging disease.

Management Considerations for Patients With Primary Refractory and Early Relapsed Diffuse Large B-Cell Lymphoma

Cassandra Duarte, MD[1] and Manali Kamdar, MD[1]

Overview

Most patients with diffuse large B-cell lymphoma (DLBCL) will be cured with up-front chemoimmunotherapy, but 30%-40% of patients will experience relapsed disease. Historically, salvage chemotherapy followed by autologous stem-cell transplant (ASCT) was the mainstay of treatment for these patients. However, research has demonstrated that patients with primary refractory or early relapsed (R/R; high-risk) DLBCL do not benefit from ASCT, prompting investigation into other options. With the advent of chimeric antigen receptor (CAR) T-cell therapy, treatment of R/R DLBCL has changed dramatically. With positive outcomes in the TRANSFORM and ZUMA-7 trials with manageable toxicity profiles, approval was obtained for lisocabtagene maraleucel (liso-cel) and axicabtagene ciloleucel (axi-cel) as second-line therapies for high-risk R/R DLBCL. However, these trials required patients to be medically fit for ASCT. In PILOT, liso-cel was deemed a reasonable treatment option for R/R transplant-ineligible patients. We recommend either axi-cel or liso-cel for fit patients with high-risk R/R DLBCL or liso-cel for unfit R/R patients as a second-line therapy. If CAR T-cell therapy is not an option, we recommend consideration of either ASCT if the patient has chemosensitive disease and is fit or clinical trial if the patient is unfit or has chemoresistant disease. If trials are not an option, alternative treatments are available. With the advent of additional therapies such as bispecific T-cell–engaging antibodies, the treatment landscape of R/R DLBCL may be upended. There continue to be many unanswered questions in the management of patients with R/R DLBCL, but given the promise of cellular therapies, outcomes are more optimistic in this group with historically dismal survival.

INTRODUCTION

Diffuse large B-cell lymphoma (DLBCL) is a heterogeneous disease with a 5-year overall survival (OS) ranging from 79.5% for stage I disease to 54.7% for stage IV disease, with a median 5-year OS of 64.6%.[1] Although two thirds of patients with DLBCL are cured with up-front immunochemotherapy regimens, such as rituximab, cyclophosphamide, doxorubicin, vincristine, and prednisone (R-CHOP), up to 30%-40% of patients will either have progression of disease during or at the end of up-front therapy (ie, primary refractory) or relapse after initial response.[2,3] Historically, the treatment of relapsed/refractory (R/R) DLBCL has been salvage chemotherapy followed by autologous stem-cell transplant (ASCT). Although ASCT has the potential to be curative, patients with primary refractory or early relapsed disease often do not reach the same levels of success with ASCT. Recent clinical trial advances and drug approvals in transplant-eligible and transplant-ineligible patients with R/R DLBCL have unleashed several novel therapeutics providing more efficacious options with manageable toxicity profiles. This review will outline these advances and highlight a proposed algorithm for the management of patients with primary refractory and early relapsing (high-risk R/R) DLBCL.

ASCT: NOT A ONE-SIZE-FITS-ALL APPROACH FOR R/R DLBCL

In 1995, the Parma trial reported results of a phase III trial evaluating fit patients younger than 60 years with relapsed intermediate- or high-grade lymphoma by the Working Formulation classification who had attained a complete response (CR) for at least 4 weeks to initial induction doxorubicin-based therapy. Salvage chemotherapy with two cycles of DHAP (dexamethasone, high-dose cytarabine, and cisplatin) followed by ASCT with carmustine, etoposide, cytarabine, cyclophosphamide, and mesna conditioning was superior to salvage chemotherapy alone with respect to 5-year event-free survival (EFS) rate (46% *v* 12%) and OS rate (53% *v* 32%). This trial solidified the role of ASCT as the standard of care in patients with second-line relapsed DLBCL and refractory patients although that group was not specifically studied.[4] Subsequently, as the phase III trials, CORAL and LY12 investigated different salvage chemotherapy regimens with some incorporating rituximab, such as rituximab, ifosfamide,

Author affiliations and support information (if applicable) appear at the end of this article.

PRACTICAL APPLICATIONS

- Although most patients with diffuse large B-cell lymphoma will be cured with up-front chemoimmunotherapy, 30%-40% of patients will relapse. Although autologous stem-cell transplant offered a second chance at a durable remission, primary refractory and early relapsed diffuse large B-cell lymphoma (DLBCL) had an extremely poor outcome.
- On the basis of randomized controlled trials, chimeric antigen receptor (CAR) T-cell therapy with axicabtagene ciloleucel or lisocabtagene maraleucel (liso-cel) is now the recommended second-line treatment for patients who are medically fit with primary refractory and early relapsed disease.
- For unfit patients with relapsed/refractory DLBCL, we recommend treatment with liso-cel therapy if available and if not, participating in a clinical trial with treatments such as bispecific T-cell engagers (BITE), or treatment with an approved agent such as tafasitamab with lenalidomide, polatuzumab-vedotin with bendamustine and rituximab, R-GemOx, or loncastuximab tesirine.
- There remain many areas for research in DLBCL including optimizing options for bridging therapy, sequencing of treatments, such as CAR T-cell and BITE therapy, and when to treat a patient who may experience a complete response during salvage chemotherapy while awaiting CAR T-cell therapy.

carboplatin, and etoposide, R-DHAP, and gemcitabine, dexamethasone, and cisplatin, and demonstrated similar efficacy across all salvage regimens.[5,6]

An important finding of the CORAL and LY.12 trials was that patients with primary refractory disease or relapsed disease within 12 months after diagnosis had significantly inferior outcomes compared with patients who relapsed after 12 months. The CORAL study highlighted that patients with R/R DLBCL within 12 months of diagnosis with previous exposure to rituximab had dismal outcomes with a 3-year progression-free survival (PFS) of only 23%.[5]

The REFINE study looked further in-depth at why patients in the rituximab era might have primary treatment failure. In this multicenter retrospective study of nearly 300 patients, ultra-high-risk features were defined as having primary progressive disease while on first-line treatment (defined as progressive disease by clinical or radiologic assessment during or within 6 weeks of completion of chemoimmunotherapy), an intermediate-high or high National Comprehensive Cancer Network International Prognostic Index score at the time of primary treatment failure, or *MYC* translocation. Of the entire cohort, patients with ultra-high-risk features had a predicted 2-year overall survival (OS) of 13.6%. Of the 132 patients who underwent ASCT, 2-year OS was directly related to the number of high-risk features, with the OS of 74.3% for patients with no ultra-high-risk features and only 10.7% for patients with two to three ultra-high-risk features.[7]

Another multicenter retrospective review of 117 patients examined the impact of double-hit (defined as *CMYC* and either *BCL2* or *BCL6* gene rearrangements) and double-expressor (defined as overexpression of *CMYC* and *BCL2* protein) status on ASCT outcomes in patients with R/R DLBCL. Both double-hit and double-expressor lymphomas were associated with poor PFS, and double-hit lymphoma was associated with poor OS post-transplantation. Notably, for patients with double-hit status, the 4-year PFS and OS were only 28% and 25%, respectively, and the 4-year PFS was 0% for both double-expressor and double-hit status.[8]

SCHOLAR-1 was an international, multicohort study that retrospectively evaluated outcomes in patients with refractory DLBCL. This analysis demonstrated that patients who were primary refractory, were refractory to two or more lines of therapy, or relapsed within 1 year of an ASCT had an overall response rate (ORR) of 26% (CR, 7%) to the next line of therapy, and the median OS was 6.3 months. Only 20% of patients were alive after 2 years.[9]

Thus, ASCT may be a potentially curative approach for some patients with R/R DLBCL; however, high-risk subgroups such as those with primary refractory disease, those with early relapse, and patients who meet the REFINE ultra-high-risk factors and double-hit gene rearrangements warrant a different therapeutic modality.

A NEW PARADIGM IN R/R DLBCL TREATMENT

Chimeric antigen receptor (CAR) T-cell therapy is a novel treatment strategy that has improved outcomes in patients with relapsed lymphomas. CAR T-cell therapy is an immune effector cell therapy where autologous T cells are genetically engineered to target CD19 antigen on lymphoma cells. Patients awaiting CAR T-cell therapy may require bridging therapy, which often comprises glucocorticoids or additional chemotherapy to maintain disease control until the products can be engineered. Before CAR T-cell infusion, patients receive lymphodepleting chemotherapy, often with fludarabine and cyclophosphamide. On the basis of phase II pivotal trials, three CAR-T constructs, namely, axicabtagene ciloleucel (axi-cel), lisocabtagene maraleucel (liso-cel), and tisagenlecleucel (tisa-cel), were initially approved by the US Food and Drug Administration (FDA) for third-line treatment of R/R LBCL (large B-cell lymphoma), demonstrating excellent responses and durable PFS and OS.[10-12] In the

ZUMA-1 trial, 111 patients with R/R LBCL were enrolled. axi-cel was administered to 91% of the cohort. The ORR was 82% with a CR rate of 54%. The 18-month OS was 52%.[10] In the TRANSCEND trial, patients with R/R LBCL were enrolled to assess the efficacy and safety of liso-cel therapy. Of the 344 patients enrolled, 78.2% received at least one dose of liso-cel. The ORR was 74% with a CR rate of 54%. The median OS was 21.1 months after a follow-up of 17. 5 months.[12] In the JULIET trial, 93 patients with R/R DLBCL were enrolled and all patients received tisa-cel therapy. The ORR was 52% with a CR rate of 40%.[11] Long-term results with over a 4-year follow-up for ZUMA-1 demonstrated a median OS of 25.8 months with a 4-year OS rate of 44% hinting at a possible cure for a subset of R/R DLBCL.[13] At a median follow-up of 40.3 months for JULIET, the ORR was 53%, with 39% of patients achieving a CR.[14] These trials demonstrated the safety, efficacy, and durability of response of CAR T-cell therapy as a third-line therapy for patients with R/R DLBCL. Given that a significant proportion of patients with heavily pretreated DLBCL achieved a durable response after CAR T-cell therapy, it was intuitive to explore the efficacy and safety of CAR T-cell therapy in the second-line high-risk R/R DLBCL setting, thus creating a paradigm shift in the treatment of DLBCL.

TREATMENT OF FIT PATIENTS WITH HIGH-RISK PRIMARY REFRACTORY AND EARLY RELAPSING DLBCL

While ZUMA-1, TRANSCEND, and JULIET demonstrated the benefit of CAR T-cell therapy after two or more lines of treatment, three pivotal phase III trials, ZUMA-7, TRANSFORM, and BELINDA, explored the use of axi-cel, liso-cel, and tisa-cel, respectively, in the second-line setting in transplant-eligible patients with primary refractory and early relapsing (high-risk R/R) DLBCL against standard investigator choice (SOC) salvage chemotherapy, followed by high-dose chemotherapy and ASCT.[15-17] ZUMA-7 and TRANSFORM met their primary end point of EFS and demonstrated superiority with manageable toxicity of CAR T-cell therapy compared with ASCT. BELINDA did not show superiority of CAR T-cell therapy to SOC. Table 1 outlines key features of these three clinical trials.

The ZUMA-7 and TRANSFORM trials showed strikingly similar efficacy for axi-cel and liso-cel compared with SOC. With a median follow-up of 24.9 months, axi-cel therapy achieved superior EFS (8.3 months *v* 2 months), ORR (83% *v* 50%), and CR (65% *v* 32%) compared with SOC.[15] In the TRANSFORM trial, the primary end point of EFS was significantly improved in the liso-cel group (10.1 months) compared with SOC (2.3 months). liso-cel therapy was associated with a higher CR (66% *v* 39%) and a longer median duration of response (not reached *v* 14.5 months) when compared with SOC. A statistically significant improvement in PFS was observed in the liso-cel group (stratified hazard ratio [HR], 0.41; 95% CI, 0.25 to 0.66; $P = .0001$).[16] The primary analysis at a median follow-up of 17.5 months continues to demonstrate excellent outcomes for liso-cel over SOC.[18] In both studies, adverse events were similar in the CAR T-cell therapy and SOC arm with the exception of more neutropenia in the CAR T arm; however, this did not translate into higher incidence of febrile neutropenia. With respect to toxicities of special interest, grade 3 or higher cytokine release syndrome (CRS) and neurotoxicity (NT) were seen in 6% and 21%, respectively, in the ZUMA-7 study and in 1% and 4%, respectively, in the TRANSFORM study.

Altogether, the abovementioned data resulted in FDA approval of axi-cel and liso-cel for second-line treatment in fit patients with primary refractory and early relapsed large-cell lymphoma in 2022.[19-21] After almost two and a half decades of suboptimal outcomes, CAR-T cell therapy represents a new standard of care for patients with high-risk R/R DLBCL.

TREATMENT OF UNFIT PATIENTS WITH R/R DLBCL

A key inclusion criterion for the trials discussed earlier was that patients had to be medically fit to be considered for ASCT in the SOC arm. Given that a large proportion of patients with R/R DLBCL may not be eligible for transplant on the basis of age or medical comorbidities, this begs the question of what is the ideal treatment for transplant-ineligible patients with R/R disease. The PILOT study, a phase II trial investigating the efficacy of liso-cel, recruited patients with R/R DLBCL who were considered ineligible for ASCT. Specifically, patients had to meet one of the following criteria: age 70 years or older, an Eastern Cooperative Oncology Group (ECOG) performance status of 2, receipt of one previous line of therapy containing an anthracycline and a CD20-targeted agent, a diffusing capacity of the lung of 60% or less, a LVEF of $<50\%$, a creatinine clearance of <60 mL/min, or transaminases two times the upper limit of normal. Seventy-four patients underwent leukapheresis, with 61 receiving liso-cel therapy. Baseline characteristics were relevant for a median age of 74 years, 26% had an ECOG of 2, and 42% had an age-adjusted IPI score of ≥ 2. Fifty-four percent of patients had refractory disease, 21% relapsed within 1 year of first-line treatment, and 25% relapsed 12 months after first-line treatment. The primary end point was ORR. With a median follow-up of 12.3 months, the ORR was 80% (95% CI, 68 to 89; $P < .0001$) and the CR rate was 54%. The median PFS was 9.03 months (95% CI, 4.17 to not reached [NR]), and the EFS was 7.23 months (95% CI, 3.22 to 22.60). Among patients who achieved CR, the median PFS was 22.60 months (95% CI, 12.98 to NR) and the EFS was 22.60 months (95% CI, 12.98 to NR). Cytokine release syndrome was seen in 38%, and NT was seen in 31%, mostly of low grade. No grade 4 or grade 5 CRS/NT was reported. Treatment-related adverse events were similar to those previously reported, and there were

TABLE 1. Phase III CAR T-Cell Therapy Outcomes

Characteristic	ZUMA-7	TRANSFORM	BELINDA
Definition of EFS	Time from randomization to the earliest date of disease progression, the commencement of new therapy, death from any cause, or a best response of stable disease up to and including the response on the day 150 assessment after randomization	Time from randomization to death because of any cause, progressive disease, failure to achieve CR or PR by 9 weeks post-randomization, or start of a new antineoplastic therapy, whichever occurs first	Time from randomization to stable or progressive disease at or after the week 12 assessment or death at any time

no study-associated deaths.[22] PILOT demonstrated that liso-cel can be an effective time-limited option for transplant-ineligible patients with R/R DLBCL. The Food and Drug Administration approved liso-cel for adult patients with LBCL who have refractory disease to first-line chemoimmunotherapy or relapse after first-line chemoimmunotherapy and are not eligible for hematopoietic stem-cell transplantation (HSCT) because of comorbidities or age.[20]

Although our recommendation for unfit patients with early relapse and primary refractory DLBCL would be to proceed with liso-cel, we understand that not all physicians and patients have access to this therapy for a variety of reasons (bridging therapy, manufacturing time, availability of slots for apheresis, access to CAR-T center, lack of caregiver). For transplant-ineligible patients without access to CAR T-cell therapy, we recommend participation in a clinical trial whenever possible. If a clinical trial is not available, then one could consider other FDA-approved regimens in R/R DLBCL such as tafasitamab with lenalidomide, polatuzumab-vedotin with bendamustine and rituximab (pola-BR), R-GemOx, or loncastuximab tesirine (Table 2). The data behind these treatments are reviewed below.

In the L-MIND trial, patients with R/R DLBCL ineligible for ASCT were treated with tafasitamab, a humanized anti-CD19 monoclonal antibody (12 mg/kg weekly for three 28-day cycles and then every 14 days until progression) in combination with lenalidomide (25 mg daily on days 1-21 of a 28 day cycle for 12 cycles) as a second-line treatment. Importantly, when the recruitment began, patients with primary refractory disease defined as no response or progressive disease within 3 months of frontline therapy were excluded. Eighty-one patients were enrolled, with 56% of patients older than 70 years; 75% of patients had stage III-IV disease, with 51% having an IPI score of $\geq$3; and 92% had an ECOG of 0-1; 18.5% of patients had primary refractory disease, 41.3% had rituximab-refractory disease, and 43.8% were refractory to their last line of treatment. After a median follow-up of 35 months, the ORR was 57.5% and the CR rate was 43%, with a median PFS of 11.6 months (95% CI, 6.3 to 45.7) and median OS of 33.5 months (95% CI, 18.3 to NR). For patients achieving a CR, median PFS and median OS were not reached. The most common grade 3 or greater treatment-related adverse events were neutropenia (49.4%), thrombocytopenia (17.3%), and febrile neutropenia (12.3%).[23,26]

Polatuzumab-vedotin is a CD79b-targeted antibody-drug conjugate with a payload of monomethyl auristatin E (MMAE), a microtubule inhibitor. In a phase Ib/II trial, pola-BR was compared against BR alone in ASCT-ineligible patients with R/R DLBCL. In previous studies, BR alone in this patient population had a median PFS of 3.6-6.7 months.[27,28] For this trial, patients with R/R DLBCL after at least one previous line of therapy were included. One hundred eighteen patients were enrolled, with 67 patients receiving therapy with pola-BR. In the pola-BR group, 82.5% had an ECOG of 0-1, with a median age of 67 years, and 45% had three or more previous lines of therapies. Of the patients receiving pola-BR, 25% had failed a previous ASCT and 30% had an insufficient response to previous therapy. After a median follow-up of 22.3 months, the PFS was 9.5 months (95% CI, 6.2 to 13.9) in the pola-BR versus 3.7 months (95% CI, 2.1 to 4.5) in the BR-alone group (HR, 0.36; 95% CI, 0.21 to 0.63; $P < .001$), and OS significantly improved, with pola-BR patients surviving 12.4 months versus BR patients surviving 4.7 months (HR, 0.42; 95% CI, 0.24 to 0.75; $P = .002$).[25]

In a retrospective review of 196 transplant-ineligible patients with R/R DLBCL, it was found that R-GemOx was a promising and well-tolerated regimen. Patients were eligible if they had progressive or stable disease during a treatment or relapse/progression within 1 year of last treatment. The breakdown between primary refractory and early relapsed was not specified. The median age was 72 years, with 63% of patients having an IPI score of $\geq$3. Sixteen percent of patients had undergone ASCT. Fifty-eight percent received R-GemOx as a second-line treatment, 23% received it as a third-line treatment, and 19% received it as a fourth-line

treatment or later. With a median follow-up of 22 months, 33% of patients achieved a CR and the median PFS was 5 months with a median OS of 10 months. There was no statistically significant difference in PFS or OS on the basis of whether R-GemOx was given in the second- or subsequent-line setting.[29]

Loncastuximab tesirine is an antibody-drug conjugate comprising a humanized anti-CD19 antibody conjugated to a cytotoxic alkylating agent, SG3199.14, which is internalized by CD19-expressing B cells to then deliver the payload, which causes interstrand DNA cross-links preventing DNA replication causing apoptosis. In the phase II LOTIS-2 trial, patients with two or more lines of treatment for DLBCL or primary refractory disease were enrolled. Of 184 patients enrolled, 39% had primary refractory disease, 24% had relapse within 3 months of first-line therapy, and 39% had relapse within 6 months of first-line therapy. The median age was 66 years, with 10% having double- or triple-hit DLBCL. The ORR was 48.3% (95% CI, 39.9%-56.7%), the median PFS was 4.9 months, and the median OS was 9.9 months. The CR rate was 24.1%, and of patients in a CR, 57% continued in a CR at the time of data cutoff.[24]

IMPLEMENTING CAR T-CELL THERAPY IN SECOND LINE FOR HIGH-RISK R/R DLBCL—ONGOING CONTROVERSY AND UNANSWERED QUESTIONS

After the approval of CAR T-cell therapy as a second-line therapy, many experts have debated if ASCT is a thing of the past for patients with high-risk R/R DLBCL who show a response (CR/PR) to salvage chemotherapy. The studies exploring CAR-T versus ASCT trials randomly assigned patients before initiating salvage therapy given historically poor rates of chemosensitivity for these subgroups and thus were not designed to answer this question. On the basis of the data outlined earlier, it is reasonable to state that patients with primary refractory, ultra-high-risk by REFINE criteria and double-hit lymphomas do not appear to benefit from ASCT even if they demonstrate chemosensitivity.

However, the best strategy for early relapsed DLBCL remains unclear, with some favoring CAR T-cell therapy and others recommending ASCT for chemosensitive patients. In a retrospective review of the Center for International Blood and Bone Marrow Transplant Research (CIBMTR) registry, the efficacy of ASCT was compared with that of CAR T-cell therapy in patients with DLBCL in a partial response after salvage chemotherapy. Four hundred eleven patients with early relapsed DLBCL were identified, with 266 having undergone ASCT while in a partial response and 145 having undergone CAR T-cell therapy. Early relapse for this population was defined as relapse or progression in $\leq$1 year from original diagnosis. The 2-year PFS was 52% for patients receiving ASCT while in a PR and was 42% for patients undergoing CAR T-cell therapy (P = .05). The 2-year OS rate was 69% in patients undergoing ASCT compared with the OS rate of 47% in those undergoing CAR T-cell therapy (P = .004). The incidence of relapse or progression was lower in the ASCT group compared with the CAR T-cell group at both 1-year (34% *v* 45%) and 2-year (40% *v* 52%) follow-ups.[30] It is important to recognize that the ASCT patients were less heavily pretreated than CAR T patients. This was a retrospective review, introducing mortality time bias. In TRANSFORM, EFS was also examined for patients who crossed over to liso-cel therapy. Of the 46 patients who crossed over, 10 had undergone ASCT. With a median follow-up of 4.1 months, the EFS was 3.4 months and the ORR was 48%, with a CR rate of 39% and OS of 7.8 months.[16] This demonstrates that although liso-cel was effective, its efficacy is less pronounced when used in the third-line setting compared with the second-line setting.

Another unanswered question is if a patient is intended to receive CAR T-cell therapy but is in a CR to salvage therapy, should that patient still receive this therapy? In a retrospective review of patients with DLBCL treated at eight academic centers receiving axi-cel or tisa-cel therapy, it was found that of 364 patients receiving CAR T-cell therapy, 33 patients received therapy in a CR (nine axi-cel, 24 tisa-cel). Of this subset of patients, 26 had measurable disease at the time of leukapheresis and went into CR after bridging therapy, with most patients receiving systemic therapy (20 patients). With a median follow-up of 16 months, 39.3% of patients had relapsed. The 1-year EFS and OS of patients were 59.6% and 81.3%, respectively, indicating that CAR T-cell therapy continued to be effective treatment even for patients in a CR at the time of T-cell infusion. In addition, the development of CRS and ICANS in this patient subset was much lower than that in patients with residual disease at the time of CAR T-cell treatment, demonstrating safety in this population.[31] This was also supported by TRANSFORM as there were nine patients who were in a CR at the time of liso-cel infusion and demonstrated favorable outcomes.

Until better prediction tools are available to determine chemosensitivity, we recommend CAR T-cell therapy in second line for patients with primary refractory and early relapsed DLBCL. However, it is reasonable to consider ASCT in early relapsed DLBCL if patients do not have access to CAR T-cell therapy or are being evaluated for consolidation therapy after having achieved a CR/PR to salvage therapy.

Often patients with R/R disease will need prompt access to treatment, but CAR T-cell production takes on average anywhere from 3 to 4 weeks. This delay in therapy necessitates the importance of establishing optimal bridging therapies. Typical therapies are steroids, salvage chemotherapy (RICE, R-GemOX, RDHAP), or polatuzumab with a preference for combination with rituximab therapy. However, this may change with the POLARIX trial. In POLARIX,

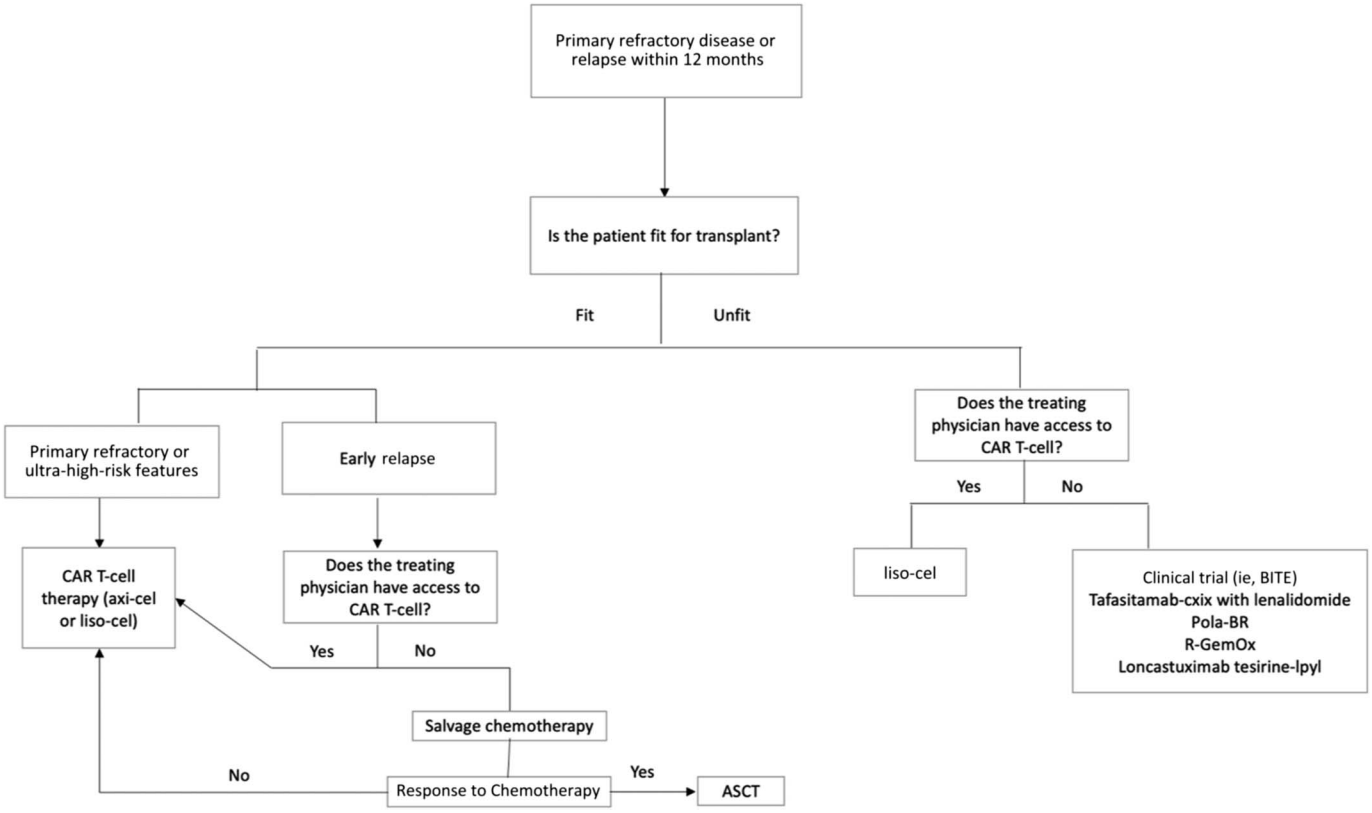

FIG 1. Proposed algorithm for treatment of primary refractory and early relapsing DLBCL. ASCT, autologous stem-cell transplant; axi-cel, axicabtagene ciloleucel; BITE, bispecific T-cell engagers; CAR, chimeric antigen receptor; DLBCL, diffuse large B-cell lymphoma; liso-cel, lisocabtagene maraleucel; pola-BR, polatuzumab-vedotin with bendamustine and rituximab; R-GemOx, rituximab, gemcitabine, oxaliplatin.

investigators compared frontline therapy in patients with untreated DLBCL with R-CHOP or pola-R-CHP. With a median follow-up of 28.2 months, pola-R-CHP patients were more likely to be alive without progression (76.7% *v* 70.2%). OS at 2 years was not significantly different between the groups (88.7% *v* 88.6%).[32] If pola-R-CHP receives approval for frontline treatment of intermediate- to high-risk DLBCL, it would prevent its use as a bridging agent. More research is required to determine ideal bridging strategies.

LOOKING INTO THE HORIZON

Although CAR T-cell therapy seems promising for the treatment of R/R DLBCL, novel strategies for treatment that may circumvent issues with production and cost are underway. Bispecific T-cell engagers (BITEs) targeting CD20 are off-the-shelf therapies that have demonstrated excellent results. There are at least four BITEs currently being studied in clinical trials, including mosunetuzumab, glofitamab, epcoritamab, and odronextamab, with glofitamab and epcoritamab having the most mature data in R/R DLBCL for review.

Glofitamab is a BITE that binds in a 2:1 fashion to C20 on B cells and CD3 on T cells, imparting greater potency. In a phase I trial of 171 patients with NHL who had undergone at least one line of treatment with no further options, 42.7% of patients had DLBCL, the median age was 64 years (range 22-85), and patients on average had three previous lines of therapy. For patients with aggressive NHL histologies, the ORR was 48% with a CR rate of 33.1%. CRS occurred in 50.3% of all patients, with most patients experiencing grade 1 (21.6%) or grade 2 (25.1%) CRS.[33] In the phase II trial, patients were treated with glofitamab for 12 cycles or until disease progression. In the cohort of 154 patients with a median follow-up of 12.6 months, 39% of patients had a CR with a median time to CR of 42 days. Seventy-eight percent of CRs were ongoing at 12 months. The 12-month PFS was 37%.[34] Recent data demonstrated that time-limited treatment with glofitamab can result in durable CR for patients with relapsed DLBCL. Of 61 patients with heavily pretreated DLBCL who had received glofitamab for 1 year with a median follow-up of 18.1 months, a majority of patients (45) remained in CR.[35]

Epcoritamab is a BITE that targets CD3 on T cells and CD20 on B cells and is subcutaneously administered. In a phase I/II trial, 157 patients with DLBCL or other aggressive NHL with two or more lines of therapy, who were ineligible for ASCT, were recruited. Patients received a median of three

lines of therapy (range, 2-11), 61.1% had primary refractory disease, and 75.8% were refractory to two or more lines of therapy; 38.9% had received previous CAR T-cell therapy. The ORR was 63.1% with a CR rate of 38.9%. Overall, epcoritamab was demonstrated to be tolerable, with the most common adverse events being CRS (49.7%), injection site reaction (19.7%), and neutropenia (17.8%).[36] While further research must be performed to compare BITEs with the standard of care, they hold promise as an off-the-shelf option for patients with DLBCL who are not transplant or CAR T-cell therapy candidates.

CONCLUSIONS

Although most patients with DLBCL are cured with first-line rituximab and anthracycline-based immunochemotherapy, a significant subset of patients experience R/R disease. With the proven benefit of CAR T-cell therapy in transplant-eligible and transplant-ineligible patients with high-risk R/R DLBCL, it is our recommendation that CAR T-cell should be the treatment of choice in patients with R/R DLBCL, if available. For patients who are medically fit with early relapse for whom CAR T-cell therapy is not an option, salvage chemotherapy with ASCT is a reasonable consideration. For medially unfit patients, we recommend treatment with liso-cel or other alternative therapies. We propose the algorithm in Figure 1 for the treatment of high-risk R/R DLBCL. Many questions remain on the impact of prolonged immunosuppression with CAR T-cell therapy, including long-term infection risk and response to vaccination. With the impending regulatory approval of BITEs, the proposed paradigm in this review may be entirely shifted in the coming years. BITE therapy has proven to be effective in early trials and holds promise as a treatment option that may be more widely available to patients as an off-the-shelf option compared with CAR T-cell therapy. While more time will be required to allow these data to mature, it would be reasonable to refer patients with relapsed disease after CAR T-cell therapy to BITE therapy. It is unclear if patients receive BITE before CAR T-cell therapy if T-cell exhaustion would limit response to CAR T-cell therapy. Given historically dismal outcomes of patients with R/R DLBCL, the rise of novel therapies including CAR T-cell therapy and BITEs holds great promise for treatment options for this historically neglected patient population.

Practical Management of Richter Transformation in 2023 and Beyond

Christine E. Ryan, MD[1] and Matthew S. Davids, MD, MMSc[1]

overview

While the past decade has witnessed unprecedented progress for patients with chronic lymphocytic leukemia (CLL), outcomes for patients with Richter transformation (RT) remain dismal. Multiagent chemoimmunotherapy regimens, such as rituximab plus cyclophosphamide, doxorubicin, vincristine, and prednisone, are commonly used, although outcomes are far poorer than observed with the same regimens used in de novo diffuse large B-cell lymphoma. The revolutionary targeted therapies approved for CLL, such as inhibitors of Bruton tyrosine kinase and B-cell leukemia/lymphoma-2, have limited activity in RT as monotherapy, and initial promising activity of checkpoint blockade antibodies was also eventually found to be ineffective as monotherapy for most patients. Over the past few years, as outcomes for patients with CLL improved, there has been a growing focus of the research community on improving our biological understanding of the underlying pathophysiology of RT and on translating these new insights into rational combination strategies that are poised to improve therapeutic outcomes. Here, we present a brief overview of the biology and diagnosis of RT, as well as prognostic considerations, before providing a summary of the data supporting various therapies that have been recently studied in RT. We then turn our attention to the horizon and describe several of the promising novel approaches under investigation to treat this challenging disease.

INTRODUCTION

While the past decade has witnessed unprecedented progress in the outcomes for patients with chronic lymphocytic leukemia (CLL), outcomes for patients with Richter transformation (RT; also known as Richter's syndrome) unfortunately remain dismal. The prognosis for this disease is nearly as poor as it was when it was first identified nearly 100 years ago. It was first described by the American pathologist Dr Maurice Richter in 1928 as a reticular cell sarcoma[1] and the condition was later named in his honor in 1964.[2] Incremental progress was made with the utilization of multiagent chemoimmunotherapy (CIT) regimens, such as rituximab plus cyclophosphamide, doxorubicin, vincristine, and prednisone (R-CHOP), although outcomes are far poorer than observed with the same regimens used in de novo diffuse large B-cell lymphoma (DLBCL). The revolutionary targeted therapies approved for CLL, such as inhibitors of Bruton tyrosine kinase (BTK) and B-cell leukemia/lymphoma-2 (BCL-2), have limited activity in RT as monotherapy, and initial promising activity with checkpoint blockade antibody monotherapy was also eventually found to be ineffective for most patients. There is cause for optimism, however. Over the past few years, as outcomes for patients with CLL improved, there has been a growing focus of the research community on improving our biological understanding of the underlying pathophysiology of RT and on translating these new insights into rational combination strategies that are poised to improve therapeutic outcomes. Here, we present a brief overview of the biology and diagnosis of RT, as well as prognostic considerations, before providing a summary of the data supporting various therapies that have been recently studied in RT. We then turn our attention to the horizon and describe several of the promising novel approaches under investigation to treat this challenging disease.

BIOLOGY

The development of RT involves a complex interplay between genetic, epigenetic, immunologic, and tumor microenvironmental factors. Retrospective studies have demonstrated that certain genetic features of a patient's CLL are associated with increased risk of development of RT. These include the presence of *TP53* aberrancy,[3] *NOTCH1* mutation,[4,5] and certain BCR stereotypes,[6] specifically subset 8 immunoglobulin heavy chain (IGHV 4-39).[7,8]

Advancements in the genetic, epigenetic, and transcriptomic profiling of RT have been made in recent years, leading to new insights into the biology of this challenging disease.[9] Owing to limited availability of primary patient samples and RT-derived cell lines, reliable murine models provide an important avenue of interrogating the biological complexities of RT. Recently, multiplexed in vivo CRISPR-Cas9 B-cell editing of recurrent CLL loss-of-function genetic drivers was

Author affiliations and support information (if applicable) appear at the end of this article.

PRACTICAL APPLICATIONS

- Signs/symptoms that should raise clinical suspicion for Richter transformation (RT) include development of a rapidly enlarging lymph node, new fevers, drenching night sweats, unintentional weight loss, and/or persistent lactate dehydrogenase elevation.
- Diagnostic work-up of suspected RT should include a positron emission tomography-computed tomography scan, biopsy of the most fluorodeoxyglucose-avid lymph node, expert hematopathology review, and, if possible, determination of IGHV clonality.
- Chemoimmunotherapy remains the most commonly used initial therapy for RT, with nonrandomized data supporting the addition of venetoclax; allogeneic hematopoietic cell transplantation does provide a chance for long-term remission.
- Significant advancements in the genetic, epigenetic, and transcriptomic profiling of RT have been made in recent years, and these new biological insights have begun to inform the design of trials investigating targeted regimens in RT.
- Such trials investigating targeted agents include Bruton tyrosine kinase inhibitors, venetoclax, immune checkpoint blockade, chimeric antigen T cell, and bispecific antibodies in various combinations, and these studies will likely pave the way for new targeted therapeutic options for RT.

shown to recapitulate the process of transformation from an indolent CLL into a large cell lymphoma.[10] This model provides a robust system in which to interrogate novel therapies as well as study potential disease resistance mechanisms; such preclinical studies may prove pivotal to informing the design of early-phase clinical trials for RT.

Several recent large genomic studies from patients' primary samples have also generated new understanding about the genetic events that underlie the transformation of CLL to RT.[11-14] In one study, paired CLL and RT whole-exome sequencing data from 52 patients yielded identification of RT-specific somatic driver mutations (including *IRF2BP2*, *SRSF1*, *B2M*, *DNMT3A*, and *CCND3*) and additional characteristics including certain recurrent copy number alterations and whole-genome doubling.[13] In another study, genome-wide sequencing was performed on serial samples from patients with CLL from the years preceding the diagnosis of RT and at time of diagnosis of RT. In a striking finding, in one patient, the malignant RT clone was identified 19 years before the time of diagnosis.[12] This phenomenon of early seeding was seen across several other patients studied. Additional genetic alterations were observed over time, suggesting a complex interplay between clonal selection and evolution.[12] Beyond genetic studies, advancements are also being made using functional precision medicine techniques. For example, a novel assay to interrogate apoptosis, BH3 profiling, was recently applied to primary CLL and RT samples, revealing insights into differences in survival dependence of these cells on various antiapoptotic proteins.[15] These inroads into the processes and pathways underpinning the development of RT will hopefully provide sound rationales for new therapeutic approaches in the future.

DIAGNOSIS

RT can occur at any point in the disease course of a patient with CLL, including in previously untreated patients on observation and even as an initial presentation of CLL; however, such cases are rare, and the vast majority of RT occurs in patients either on active CLL treatment or progressing after previous treatment. Early in the development of targeted therapies for CLL, there was some concern that RT may be developing more frequently on the newer drugs compared with patients treated with CIT alone. With additional research, this proved not to be the case—for example, a study by the German CLL Study Group retrospectively analyzed the incidence of RT across their portfolio of chemotherapy and CIT trials and found the rate to be in the range of 4%,[16] and in other retrospective analyses of patients with CLL treated with targeted therapies, the rate of RT similarly averages about 4%.[17-20]

The diagnosis of RT requires both appropriate clinical suspicion and diagnostic evaluation. Patients who develop RT may present with B symptoms (fevers, drenching night sweats, unintentional weight loss), new physical deterioration, rapid and/or discordant growth of a particular lymph node conglomerate, and/or a sudden and significant rise in lactate dehydrogenase (LDH). As CLL disease progression is usually indolent, the pace of these changes can be a major clue that RT is present, and in such patients, prompt diagnostic testing to evaluate for RT is warranted. In a large retrospective study of patients with CLL treated with ibrutinib, independent prognostic variables that increased the likelihood of the development of RT at disease progression were progression on active treatment, elevated LDH, and lymphadenopathy without lymphocytosis.[21]

An important initial diagnostic step is to obtain a positron emission tomography-computed tomography (PET/CT) scan, as lymphadenopathy because of CLL typically has a low level of fluorodeoxyglucose (FDG) avidity. Highly FDG-avid nodes should prompt suspicion for RT; however, the

differential diagnosis in such cases also includes transformation events not classically categorized as RT, including Hodgkin transformation (HT) and plasmablastic lymphoma. Additionally, patients with CLL are at increased risk for second malignancies, including solid tumors, so this must also remain in the differential diagnosis. Once the PET/CT is performed, a biopsy should be directed to the site of highest FDG avidity, even if this is not the most accessible site for biopsy. For example, a patient with low-moderately FDG-avid inguinal lymphadenopathy but with a highly FDG-avid retroperitoneal lymph node conglomerate should have a biopsy of the retroperitoneal mass, as biopsy of an inguinal node that shows CLL could be falsely reassuring and does not rule out the presence of RT elsewhere. Typically, a tissue biopsy completed through a core needle approach by an interventional radiologist is sufficient to make the diagnosis of RT, although an inconclusive biopsy result in the setting of a case with high clinical suspicion for RT should prompt consideration of either repeat core needle biopsy or, if feasible, excisional surgical biopsy. Occasionally, patients with RT will present with rapidly evolving cytopenias, and in that case, a bone marrow biopsy can be helpful to make the diagnosis of RT.

It should be noted that pathologic diagnosis of RT can be challenging, particularly in patients with *TP53*-aberrant CLL and those who are progressing on targeted agents, such as BTK inhibitors. In such cases, a main diagnostic confounder can be accelerated CLL, which can mimic RT, but requires a different therapeutic approach (ie, using CLL-directed therapy instead of RT-directed therapy). To be considered RT, the biopsy must demonstrate sheets of large B cells by immunohistochemistry. One retrospective study found that nearly 20% of cases described as RT locally could not be confirmed on central pathologic review,[22] so, when possible, it is encouraged to send a biopsy in a patient with CLL suspected to have RT for pathologic review at a center with specialized hematopathologists. Molecular characterization, including clonal relatedness through IGHV analysis, should be determined whenever possible as this has important prognostic implications (see below).

An important nuance to appreciate when interpreting the results of PET/CT scans when RT is suspected is that the predictive value of FDG avidity may vary depending on the type of previous therapy. For example, in patients treated only with previous CIT, the sensitivity and specificity of PET/CT with SUV values >10 were high at 91% and 95%, respectively.[23] By contrast, in a prospective study of 167 patients who progressed after ibrutinib or idelalisib and underwent a PET/CT as part of the screening evaluation for a clinical trial of venetoclax treatment, the sensitivity and specificity of SUV ≥10 were only 71% and 50%, respectively.[24] Several of the patients in this study with high SUVs that were concerning radiographically for RT underwent lymph node biopsy and were found to have accelerated CLL. These patients were then spared undergoing more aggressive CIT regimens used in RT, which are generally ineffective for accelerated CLL, and could instead be treated with standard-of-care CLL-directed therapies, which are recommended for the effective management of accelerated CLL. Thus, the decreased predictive power of PET/CT in the targeted agent era further emphasizes the crucial role that histological diagnosis plays in making a diagnosis of RT.

PROGNOSIS

The prognosis for RT remains dismal, with retrospective studies consistently reporting a median overall survival (OS) of only 6-12 months.[16,25-28] Although data in the targeted therapy era are more limited, the outcomes do not appear to be improving. For example, in a multicenter, retrospective cohort of 71 patients with CLL who developed RT while receiving treatment with a novel agent (mostly, BTKi or venetoclax), the median OS was only 3.5 months.[29]

An important feature of RT that ties together both pathophysiology and prognosis is the clonal relation to the preexisting CLL. Clonality can be determined by comparison of the *IGH V-D-J* gene rearrangement. About 80% of RT is clonally related, whereas 20% of RT is clonally unrelated.[3,30] IGHV gene sequencing is a reliable way to assess clonal relationship, but if not available, then comparison of kappa versus lambda restriction can, in some cases, provide at least some insight into the potential clonal relationship. A difference in light chain restriction suggests the RT is not clonally related. Clonality has significant implications for prognosis. One retrospective analysis demonstrated that patients with clonally unrelated RT had a median survival of approximately 5 years, whereas clonally related RT had a much shorter median OS of only 14 months.[3] Closely intertwined is the observation that the number of lines of previous CLL-directed therapy is associated with prognosis.[26,28] In a large, single-center, retrospective analysis, CLL-treatment–naïve patients who developed RT had a median OS of 46.3 months compared with a median OS of only 7.8 months in previously treated patients with CLL who developed RT.[28]

The RS score is a prognostic scoring system, which was built from a retrospective analysis of 130 patients with RT treated at MD Anderson Cancer Center and identified five characteristics that were independent predictors of shorter survival: Zubrod performance status >1, LDH >1.5 times the upper limited of normal, platelet counts $<100 \times 10^9$/L, tumor size ≥5 cm, and >1 previous therapy.[25] This score was subsequently validated in two independent cohorts where survival outcomes indeed stratified by this RS score.[3,26]

Notable subsets of CLL transformation are Hodgkin lymphoma and a cutaneous-only form of RT. Patients with HT have a more favorable prognosis than transformation to DLBCL. In a multicenter retrospective analysis of 94 patients

with transformation to HL, the 2-year OS after HT diagnosis was 72%; in those patients who received standard doxorubicin, bleomycin, vinblastine, and dacarbazine–based therapy, responses were durable, with a reported median OS of 13.2 years.[31] Cutaneous-only RT is a rare extranodal presentation of RT, with literature limited to case reports and case series, but may have a more indolent nature if confined only to the skin.[32]

MANAGEMENT

Approach in Clinical Practice

CIT, with the regimen of R-CHOP, remains the most commonly used initial treatment for RT in clinical practice. R-CHOP was initially investigated prospectively in a phase II study of 15 patients, which reported an overall response rate (ORR) of 67% (complete response [CR] rate of 7%).[33] Responses were generally not durable, with a median progression-free survival (PFS) of only 10 months. Investigation of ofatumumab in combination with CHOP yielded similar results, with an ORR of 46% (CR rate 27%) and median PFS of 6 months.[34] Additional cytarabine-based CIT regimens have been explored,[35] including the combination of oxaliplatin, fludarabine, cytarabine, and rituximab.[36,37] In these studies, the alternate CIT regimen did not significantly improve efficacy and was associated with considerable toxicity. The ORR with the regimen of rituximab, etoposide, prednisone, vincristine, cyclophosphamide, and doxorubicin (R-EPOCH) was reported to be 39%, with a PFS of 3.5 months and median OS of only 5.9 months.[38] In total, although no regimen has been demonstrated to achieve superiority (or inferiority) compared with R-CHOP, on the basis of the historical management of DLBCL, the most commonly used first-line treatment for RT remains R-CHOP.

Role of Transplant

For patients who achieve a remission to initial therapy, hematopoietic cell transplantation (HCT) presents an opportunity for potential long-lasting remission, although prospective data in this area are limited. One of the first studies to report on outcomes of allogeneic HCT (alloHCT) and autologous HCT (autoHCT) in RT was a single-institution retrospective study of 20 patients who underwent HCT as either a consolidative therapy or a salvage therapy.[25] For patients who underwent alloHCT while in remission, the estimated 3-year OS was encouragingly about 75% (although with a small sample size of only seven patients). Notably, the estimated 3-year OS was only 27% for those patients who responded to initial therapy but did not proceed to alloHCT, highlighting the potential benefit of proceeding to alloHCT in remission.

A subsequent retrospective analysis examined alloHCT and autoHCT in patients with RT and reported a 3-year PFS rate of 45% in those undergoing autoHCT versus 27% in alloHCT.[39] However, notably 82% of patients were in remission at the time of autoHCT versus only 60% of those undergoing alloHCT. Recent retrospective studies of patients with RT undergoing alloHCT have reported outcomes ranging from a 4-year PFS of 39%[40] to a 2-year PFS of 65% with reduced-intensity conditioning.[41] One of the largest recent retrospective studies of alloHCT in patients with RT (118 patients) demonstrated that disease status at the time of HCT was significantly associated with outcomes.[42] The 3-year PFS of patients in CR at the time of alloHCT was favorable at 66%, whereas it was 43% in patients in PR at the time of HCT and only 5% in patients with resistant disease. In this study, the 3-year PFS of patients who underwent autoHCT was 48%. Notably, there have been no prospective studies directly comparing autologous versus allogeneic transplantation; however, given that patients with RT have concomitant CLL and alloHCT as opposed to autoHCT can achieve durable remissions for CLL, alloHCT with reduced-intensity conditioning remains the preferred transplantation approach.

New Directions of Treatment for RT

The emergence of targeted therapies that are being effectively used in CLL and across the spectrum of B-cell non-Hodgkin lymphomas (NHL) has raised the hope that these drugs may also improve outcomes for RT. Here, we will first review the data on targeted therapies investigated as monotherapy, which have ranged from small-molecule inhibitors to immunotherapies, including immune checkpoint inhibitors, bispecific antibodies, and chimeric antigen receptor T-cell (CAR-T) therapy. We will then summarize combination strategies with available data.

Targeted Agent Monotherapies

BCL-2 inhibition. One of the first pathways to be explored with targeted agent monotherapy in RT was the intrinsic (mitochondrial) pathway of apoptosis, which is governed by the interaction of the BCL-2 family of proteins. In the phase I study of the oral BCL-2 inhibitor venetoclax, a dedicated cohort of seven patients with RT was included.[43] Three of the seven patients achieved response, suggesting some biological activity of the drug in this disease; however, these responses were for the most part relatively short-lived, and therefore, although the study was a proof of principle that BCL-2 inhibition (BCL-2i) has activity in RT, it also suggested that future studies using BCL-2i to treat RT should use the drug as part of a combination strategy.

BTK inhibition. **Covalent BTK inhibitors.** Although covalent BTK inhibitors, such as ibrutinib, acalabrutinib, and zanubrutinib, have revolutionized the treatment armamentarium for CLL,[44-46] the outcomes for patients with RT treated with these agents as monotherapy remain less promising. For example, in a small, retrospective series of four patients with RT treated with ibrutinib, three achieved response (one CR,

two PR), but the median treatment duration was only 6.1 months,[47] and in another case series of two patients, one patient had excellent disease response whereas the other patient had primary refractory disease to ibrutinib.[48]

In a phase I/II study of acalabrutinib that enrolled 25 patients with RT, while the ORR was 40%, the median duration of response (DOR) was only 6.2 months and median PFS was short at 3.2 months.[49] The activity of zanubrutinib as montherapy in RT was recently reported in 13 patients, with eight patients (62%) achieving a response (two patients achieved a CR). The median PFS and OS were favorable at 17.3 months and 29.3 months, respectively.[50]

Noncovalent BTK inhibitors. Pirtobrutinib and nemtabrutinib are noncovalent BTK inhibitors that have been studied in RT. These drugs inhibit BTK through distinct pharmacologic properties compared with covalent BTK inhibitors,[51] and they thereby have the potential to be used effectively in settings of BTKi resistance in CLL (ie, C481S-mutant *BTK*). Pirtobrutinib, a highly selective BTKi with a long half-life that enables continuous BTK inhibition, was investigated as monotherapy in RT in a dedicated cohort of the phase I/II BRUIN study. In recently reported results of 75 response-evaluable patients, the ORR was 52% with a CR rate of 10%.[52] Despite these encouraging response rates, the median PFS was short at 3.7 months. As seen across a total cohort of 773 patients including those with other B-cell malignancies, pirtobrutinib was well-tolerated, with low rates of severe adverse events (AEs). Interestingly, although these patients were relatively heavily pretreated with a median of four lines of previous CLL and RT therapy, the median OS was 13.1 months. This substantially longer median OS than median PFS suggests that pirtobrutinib may effectively serve as a bridge to other therapies such as allogeneic transplantation, which have the potential to provide durable benefit for some patients.

The results for six patients with RT treated with nemtabrutinib were reported in the BELLWAVE-001 study, with an encouraging ORR of 50% (three patients achieved a PR).[53] This noncovalent BTKi binds with similar potency to C481-mutant *BTK* and wild-type *BTK* but is less selective than pirtobrutinib, additionally having activity against SRC, ERK, and AKT; notably, it can also inhibit signaling downstream of PLCγ2.[54] In the recently reported results of a phase II expansion study across B-cell malignancies, the toxicity profile included fatigue, constipation, dysgeusia, cough, nausea, and pyrexia as the most common treatment-related AEs.[55]

Immune-Based Therapeutic Approaches as Monotherapies

PD-1 blockade. Given the high expression of PD-1 on RT cells, there is a promising rationale for investigation of immune checkpoint blockade in RT. Single-agent pembrolizumab was initially reported to have moderate activity in a small case series of nine patients with RT-DLBCL.[56] The ORR was 44% (one patient achieved a CR) with a median OS of 10.7 months, and immune-related AEs, including liver toxicities and pneumonitis, were observed in only a small proportion of patients. In a subsequent phase II study of pembrolizumab monotherapy in RT (KEYNOTE-170), the results were less promising. In 23 patients, the ORR was only 13% (4% CR) with a median PFS of 1.6 months and median OS of 3.8 months.[57] Notably, two of the three patients who responded had classical Hodgkin lymphoma histology rather than DLBCL. Thus, PD-1 blockade as monotherapy is unlikely to provide meaningful benefit in RT. Given the immune dysfunction inherent in CLL, if a future role is to be identified for checkpoint blockade in RT, it is likely that it will be as part of a combination strategy where the combination partner is able to help reduce the CLL-driven immune suppression and thus allow the checkpoint blockade to enhance antitumor immunity (see below).

Anti–CD19-directed CAR-T therapies. Given anti-CD19 CAR-T therapy can be effective even in patients with highly refractory de novo DLBCL,[58] there is a strong rationale to explore this approach in RT. To our knowledge, to date, there are no robust prospective data on the utility of CAR-T in RT specifically, although the early results available do appear to hold some promise. One small prospective study investigating an institutionally produced CD19-directed CAR-T product enrolled eight patients with transformed CLL.[59] Of the six patients with DLBCL-RT, four achieved a CR. For the four patients who responded, at a median follow-up of 5.5 months (range, 4-10 months), all were alive at last follow-up, and two patients underwent alloHCT. Additional data supporting the potential role of anti-CD19 CAR-T therapy in RT include an early report of axicabtagene ciloleucel (axi-cel) in which one patient achieved a PR, but response duration was only 1 month,[60] and a study of the product JCAR017 in which five patients with RT were treated and three patients achieved a response on day 28 restaging (two CRs, one PR).[61] In a recent institutional retrospective cohort review of the use of commercially available axi-cel, eight of nine patients responded, including five patients who achieved a CR.[62] One patient proceeded to a consolidative alloHCT, although the median follow-up was only 6 months. The expected CAR-T–associated AE of cytokine release syndrome (CRS) was observed in all patients (for eight patients, $\leq$ grade 2; one patient with grade 4 CRS). Immune effector cell–associated neurotoxicity syndrome of $\geq$ grade 3 occurred in three patients. A prospective study of the anti-CD19 CAR brexucabtagene autoleucel (brexu-cel) that includes patients with relapsed/

refractory (R/R) RT is now enrolling (ZUMA-25; ClinicalTrials.gov identifier: NCT05537766).

Bispecific antibodies. Bispecific T-cell–engaging antibodies (BsAbs), which contain a tumor antigen-binding domain and a CD3-binding domain, are designed to bring tumor cells in close proximity to effector T cells, thereby leading to direct tumor cell lysis. There are three BsAbs with reported efficacy in RT at present: blinatumomab, glofitamab, and epcoritamab. The phase II BLINART study investigated blinatumomab, a CD19/CD3 BsAb, in previously untreated DLBCL-RT and used a PET-CT response-adapted approach, whereby patients who did not achieve a CR after two initial cycles of R-CHOP proceed to induction with blinatumomab.[63] In 39 patients who initiated treatment with R-CHOP, 25 went on to receive blinatumomab, with an ORR of 36% (9/25). In another phase II study of blinatumomab in RT, nine patients were treated, with two patients achieving a response (one CR, one PR); the median survival was 10.3 months.[64]

Glofitamab and epcoritamab are CD20/CD3-targeting BsAbs. Glofitamab, a bivalent antibody with two anti–CD20-binding domains, has demonstrated highly promising efficacy in heavily pretreated patients with de novo DLBCL.[65] The phase I study included 10 patients with RT, of whom six patients were evaluable for efficacy; three achieved a CR, and two achieved a PR.[66] Epcoritamab is a monovalent CD20/CD3 BsAb that has also demonstrated a high level of efficacy in R/R de novo DLBCL.[67] An expansion cohort of the ongoing EPCORE CLL-1 phase Ib/II study specifically enrolled patients with RT. Six of the 10 patients responded, with five of those six patients achieving CR.[68] Glofitamab and epcoritamab are both well-tolerated for most patients, with the most notable AE of this class of therapies being low-grade CRS. Larger numbers of patients with longer follow-up will be needed to understand the potential for using BsAbs in RT, but the initial data do appear to be promising.

ROR1-targeting antibody-drug conjugate. The receptor tyrosine kinase-like orphan receptor 1 (ROR1) is a transmembrane oncofetal protein present on the surface of CLL and RT cells,[69] and investigations of ROR1-targeting antibodies are underway. One potential advantage of this target is that it is not expressed on other normal hematopoietic cells, including B cells, so this approach has the potential to be less immunosuppressive. The WAVELINE-001 study investigated zilovertamab vedotin, an anti-ROR1 ADC containing the antimicrotubule agent monomethyl auristatin E (MMAE) as a payload, in patients with NHL. Recently reported results included seven patients with RT, four of whom responded, with a median DOR of 2.8 months.[70] Treatment-related AEs included neutropenia, fatigue, nausea, and peripheral sensory neuropathy, consistent with the expected profile of an MMAE-containing ADC.

Novel Agent Therapies—Combination Approaches

Given the highly refractory nature of RT, and the modest activity seen with all monotherapies explored to date, to our knowledge, achievement of durable disease remission will likely require a combination therapeutic approach; there are several such strategies currently under investigation. Some build on the current standard-of-care CIT backbone while others are entirely based on combinations of targeted agents, and many incorporate immune-based approaches. In the following sections, we will focus primarily on those studies with available results, and we also include some discussion of ongoing studies without results reported yet. Figure 1 provides an overview of the spectrum of combination studies in RT.

Combination of novel agents with CIT. There are several studies investigating novel agents in combination with a CIT backbone; we recently published the results of a multicenter, phase II study of venetoclax in combination with dose-adjusted EPOCH-R, with venetoclax added via an accelerated ramp-up in cycle 2.[71] The rationale of this approach is that because venetoclax demonstrated some single-agent activity in RT,[43] it may have the potential to make RT cells more primed to undergo apoptosis. By combining venetoclax with CIT, we hypothesized that there would be a chemosensitization effect that enhanced the already established activity of CIT to treat RT. In the 26 patients enrolled, the ORR was 61.5% with a CR rate of 50%, and in the 20 patients who received venetoclax (six patients did not proceed beyond the first cycle of CIT alone), 65% (13/20) achieved CR. The OS in all patients was 19.6 months; eight patients successfully proceeded to consolidative alloHCT with 11 remaining on venetoclax monotherapy maintenance. Toxicity with the R-EPOCH backbone was notable for hematologic and infectious complications, particularly in older patients and those with preexisting medical comorbidities. To assess whether keeping the venetoclax but deintensifying the CIT backbone might lead to better tolerability while still preserving the potential for chemosensitization, a new cohort investigating venetoclax plus R-CHOP (VR-CHOP) is ongoing. With the promising results from the initial VR-EPOCH cohort, using VR-EPOCH or VR-CHOP for a fit patient with RT is a reasonable consideration in clinical practice, given that all the agents are already approved and accessible for use in patients with CLL.

Another approach being evaluated is the combination of BTKi with CIT. Given that acalabrutinib did have some single-agent activity as described earlier and was also well-tolerated in patients with RT, it was hypothesized that it could be efficacious to add it to a CIT backbone to improve the quality of response. The ongoing STELLAR trial is a randomized study investigating the combination of

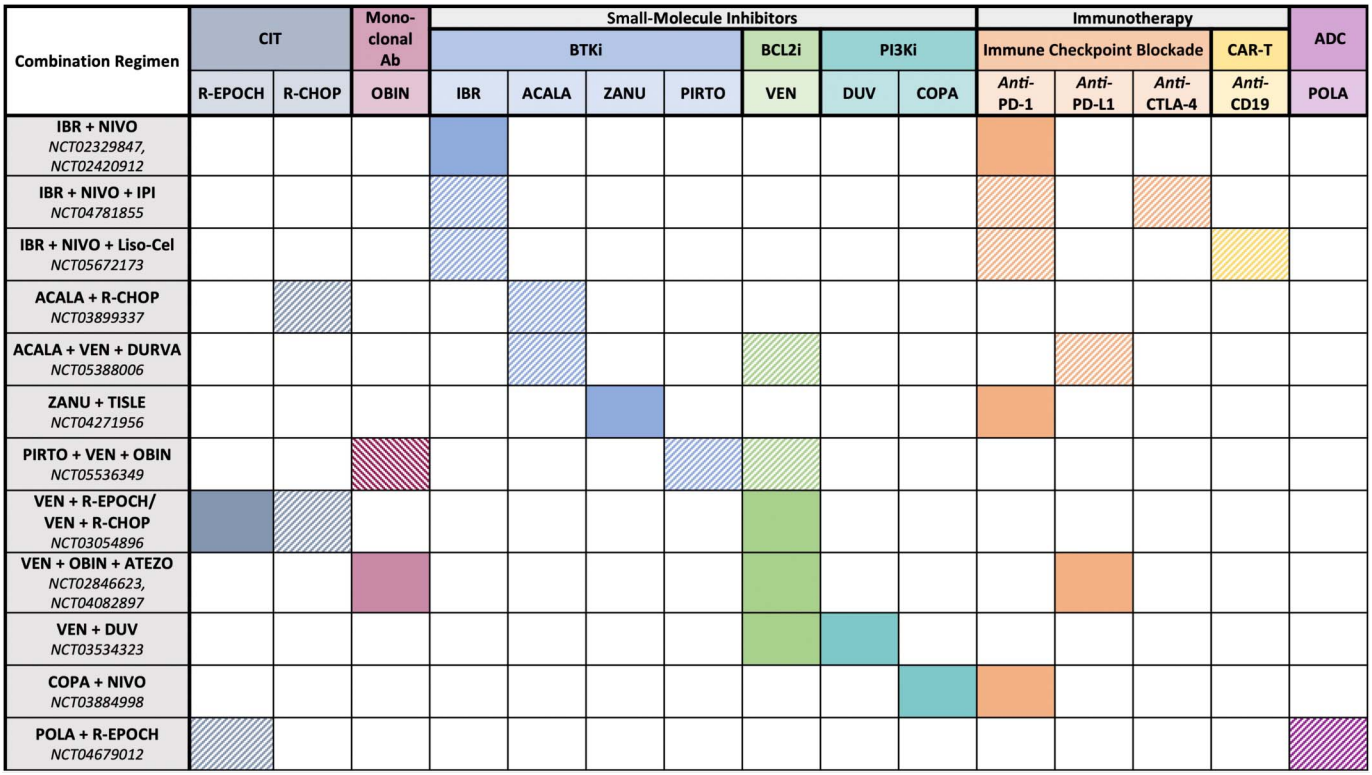

FIG 1. Novel agent combination treatment regimens under investigation for the treatment of Richter transformation. Solid fill indicates results reported. Hashed lines indicate trial enrollment ongoing with no reported results yet. Ab, antibody; ACALA, acalabrutinib; ADC, antibody-drug conjugate; ATEZO, atezolizumab; BCL2i, B-cell leukemia/lymphoma-2 inhibitor; BTKi, Bruton tyrosine kinase inhibitor; CAR-T, chimeric antigen receptor T-cell; CIT, chemoimmunotherapy; COPA, copanlisib; CTLA-4, cytotoxic T-cell lymphocyte-4; DURVA, durvalumab; DUV, duvelisib; IBR, ibrutinib; IPI, ipilimumab; Liso-cel, lisocabtagene maraleucel; NIVO, nivolumab; OBIN, obinutuzumab; PIRTO, pirtobrutinib; POLA, polatuzumab vedotin; R-CHOP, rituximab plus cyclophosphamide, doxorubicin, vincristine, and prednisone; R-EPOCH, rituximab plus etoposide, prednisone, vincristine, cyclophosphamide, and doxorubicin ; TISLE, tislelizumab; VEN, venetoclax; ZANU, zanubrutinib.

acalabrutinib and R-CHOP versus R-CHOP alone in RT.[72] This trial is particularly noteworthy given that, to our knowledge, it will be the first randomized, controlled trial dedicated solely to RT ever to be reported.

Combination of BCL-2i with phosphoinositide 3-kinase inhibition. Rationale for this combination includes preclinical data demonstrating that phosphoinositide 3-kinase (PI3K) inhibition enhances the functional dependence of CLL cells on the protein BCL-2 for their survival.[73] In addition, analysis of primary CLL cells from patients treated with the delta/gamma PI3Ki duvelisib suggested increased sensitivity to venetoclax.[74] Furthermore, preclinical studies in RT-patient-derived xenograft models demonstrated synergistic effects of the combination of venetoclax and duvelisib.[75] We are currently conducting an ongoing phase I/II study of duvelisib and venetoclax in patients with R/R CLL and RT. Four of the eight patients with RT enrolled thus far have responded, with two of those four achieving CR. Two of the responders proceeded to cellular therapy (one with CAR-T and one with alloHCT) and have had durable remission, suggesting the potential of regimens, such as BCL-2i and PI3Ki, as a bridge to therapies with curative potential.[76]

Combination of small-molecule inhibitors with immune checkpoint blockade. Preclinical studies demonstrated enhanced antitumor effects when combining BTK inhibitors with PD-1/PD-L1 blockade,[77] and, to our knowledge, there have been two studies to date that have reported results of the combination of ibrutinib and nivolumab. The first included 20 patients with RT as part of a larger phase II study investigating this combination in several B-cell malignancies.[78] Patients were required to have received at least one previous line of RT-directed therapy, and previous ibrutinib treatment was an exclusion criterion. The ORR was promising at 65%, with 10% of patients achieving CR; however, the median DOR and PFS were short at 6.9 and 5.0 months, respectively. A second phase II study investigated the combination of ibrutinib and nivolumab in patients with either previously untreated or R/R RT.[79] Of the 24 patients enrolled, 58% were previously untreated for RT, although 54% (13/24) had received a previous BTKi. The ORR was 42% with a CR rate of 34%, and a median OS of

13 months; however, efficacy outcomes did differ by previous treatment status, with the median OS for the 14 patients who were treatment-naïve for RT being 24.1 months compared with 9.1 months in the 10 patients who had R/R disease.

The CLL-RT1 trial similarly investigates the combination of BTKi with PD-1 blockade, but with the second-generation covalent BTKi zanubrutinib and the PD-1 inhibitor tislelizumab.[80] This phase II multicenter trial has now completed enrollment (estimated enrollment 57 patients), and in preliminary efficacy results of seven patients, three patients were reported to have responded (one CR, two PR), with a median and OS of 2.9 months and 15.4 months, respectively.[50]

A different approach currently under investigation is a combination of the pan-PI3K inhibitor copanlisib with nivolumab in an ongoing phase I study that has now enrolled 14 patients with RT.[81] In this heavily pretreated patient population, the ORR was 29% (two CR and two PR). This study additionally includes patients with transformed follicular lymphoma, and across all 19 efficacy-evaluable patients, the median time on treatment was 3 months (range, 1-20 months). The most common grade 3-4 AEs in all 22 patients in the study were hematologic (neutropenia, lymphopenia, anemia, thrombocytopenia), and nonhematologic grade 3-4 AEs included hypertension (14% of patients) and diarrhea (9% of patients).

Investigation of the triplet of atezolizumab (PD-L1 blockade), venetoclax, and obinutuzumab is ongoing in two studies. In the multicenter international study MOLTO, preliminary safety results of 14 patients have been reported with the most common AEs being hematologic.[82] A separate single-institution phase II study of this combination has reported promising preliminary efficacy results.[83] Of eight patients enrolled, seven patients had previously untreated RT and all responded (five CR, two PR), with a median PFS of 13.0 months. Three patients successfully proceeded to a consolidative alloHCT.

CONCLUSION

In summary, the practical management of RT in 2023 still utilizes long-standing historical approaches to treatment while leveraging new targeted therapies. As shown in Figure 2, appropriate clinical suspicion should prompt diagnostic work-up, with a biopsy essential for diagnosis. Given the histopathologic challenge RT presents, expert pathology review should be obtained whenever possible. We strongly encourage clinical trial enrollment—even in the frontline setting—given the historically poor outcomes with CIT regimens. For patients who are fit, alloHCT represents the only proven modality that can provide highly durable remission at present, with outcomes associated with the depth of response entering transplant. Thus, in such patients, the primary goal of frontline treatment is to achieve CR before transplant, leveraging novel agents if needed (Fig 2).

Notably, much of the current approach management of RT is based on either single-arm studies or retrospective data, with no randomized-controlled trials reported to date, to our knowledge. Furthermore, in nearly all prospective studies either reported or ongoing, the sample sizes are limited, thus establishing that a clear new standard of care in RT will likely remain challenging in the near future. In the longer term, if the field is able to coalesce around a limited number of the most promising regimens, randomized phase III studies will be needed to define a true standard-of-care approach.

While RT remains one of the largest clinical unmet needs in the field of B-cell NHL, the new biological insights over the past few years have the potential to usher in a new era of effective targeted therapeutics. Parallel advancements in the development of novel targeted agents in the clinic provide the opportunity to leverage our increased understanding of the biological mechanisms underlying this disease to pursue rational, effective targeted agent combinations. These encouraging developments bring renewed hope that improved outcomes in RT may be on the horizon.

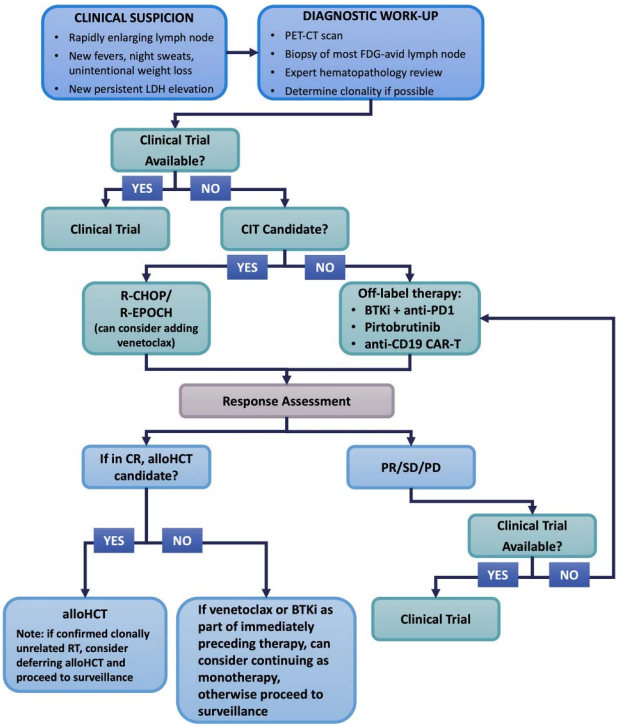

FIG 2. Summary of the practical management of Richter transformation in 2023. alloHCT, allogeneic hematopoietic cell transplantation; BTKi, Bruton tyrosine kinase inhibitor; CAR, chimeric antigen receptor; CIT, chemoimmunotherapy; CR, complete response; FDG, fluorodeoxyglucose; LDH, lactate dehydrogenase; PD, progressive disease; PET-CT, positron emission tomography-computed tomography; PR, partial response; R-CHOP, rituximab plus cyclophosphamide, doxorubicin, vincristine, and prednisone; R-EPOCH, rituximab, etoposide, prednisone, vincristine, cyclophosphamide, doxorubicin; RT, Richter transformation; SD, stable disease.

Spotlight on Small-Cell Lung Cancer and Other Lung Neuroendocrine Neoplasms

Lynnette Fernandez-Cuesta, PhD[1]; Alexandra Sexton-Oates, PhD[1]; Leyla Bayat, MD[2]; Matthieu Foll, PhD[1]; Sally C.M. Lau, MD, MPH[2]; and Ticiana Leal, MD[3]

overview

Lung neuroendocrine neoplasms (NENs) encompass a spectrum of neoplasms that are subdivided into the well-differentiated neuroendocrine tumors comprising the low- and intermediate-grade typical and atypical carcinoids, respectively, and the poorly differentiated, high-grade neuroendocrine carcinomas including large-cell neuroendocrine carcinomas and small-cell lung carcinoma (SCLC). Here, we review the current morphological and molecular classifications of the NENs on the basis of the updated WHO Classification of Thoracic Tumors and discuss the emerging subclassifications on the basis of molecular profiling and the potential therapeutic implications. We focus on the efforts in subtyping SCLC, a particularly aggressive tumor with few treatment options, and the recent advances in therapy with the adoption of immune checkpoint inhibitors in the frontline setting for patients with extensive-stage SCLC. We further highlight the promising immunotherapy strategies in SCLC that are currently under investigation.

INTRODUCTION

Lung neuroendocrine neoplasms (NENs) account for up to 25% of all lung cancers and can be subdivided into (1) well-differentiated neuroendocrine tumors (NETs, 2%), comprising low-grade typical and intermediate-grade atypical carcinoids (ACs), and (2) poorly differentiated, high-grade neuroendocrine carcinomas (NECs) including large-cell neuroendocrine carcinomas (LCNECs, 3%) and small-cell lung carcinoma (SCLC, 20%). Each of these lung NEN subtypes shows different behavior in terms of clinical presentation, prognosis, and etiology. SCLC and LCNEC are smoking-related, displaying aggressive biologic behavior, whereas highly metastatic tumors with poor prognosis, typical carcinoids, and ACs have thus far an unclear association with smoking and are less aggressive, with longer survival.[1,2] Although the incidence and prevalence of lung NETs have increased markedly in recent years,[3] LCNEC and pulmonary carcinoids are still the rare entities of lung NENs and, consequently, considered orphan diseases because of the limited basic biological and clinical knowledge.

MORPHOLOGICAL FEATURES

On the basis of the recent WHO histological classification of thoracic tumors,[1] SCLC is a malignant epithelial tumor composed of small cells with scant cytoplasm, finely granular nuclear chromatin, and absence of or inconspicuous nucleoli, with a high mitotic count and frequent necrosis. Most SCLCs express neuroendocrine (NE) markers. Combined SCLC has an additional component of non–small-cell lung carcinoma (NSCLC), which may include large-cell neuroendocrine carcinoma (LCNEC), adenocarcinoma, squamous cell carcinoma, large-cell carcinoma (LCC), spindle cell carcinoma, or giant cell carcinoma. In the case of LCNEC, large cells should make up $\geq$10% of the tumor for it to be classified as combined SCLC/LCNEC or combined SCLC and LCC. LCNEC is a high-grade NSCLC with NE morphology and a mitotic count of $>$10 mitoses/2 mm^2, which expresses one or more NE immunohistochemical markers. Combined LCNEC is an LCNEC with components of adenocarcinoma, squamous cell carcinoma, or spindle or giant cell carcinoma. Finally, carcinoid tumors are NE malignancies with a well-differentiated organoid architecture. There are two subtypes: typical carcinoids (carcinoid tumors with $<$2 mitoses/2 mm^2 and lacking necrosis) and ACs (carcinoid tumors with 2-10 mitoses/2 mm^2 and/or foci of necrosis, usually punctate; Fig 1).

Contrary to gastrointestinal/pancreatic NETs, where the proliferation marker Ki-67 is used to stratify patients for therapeutic decisions, its main role in lung NENs is to help distinguish NETs from NECs in small biopsies. Documenting Ki-67 for lung NETs may also be useful in the metastatic setting. Otherwise, mitotic counts and necrosis remain the main diagnostic criteria in primary resected lung NET basically because definite cutoffs for Ki-67 are yet to be identified.[1]

PRACTICAL APPLICATIONS

- Recent biological findings push toward a future morphomolecular classification, although they have not yet fully translated into novel therapeutic options for all subtypes.
- The optimal systemic treatment for patients with stage IV large-cell neuroendocrine carcinoma is yet to be defined, with both small-cell lung carcinoma (SCLC) and non–small-cell lung carcinoma systemic therapy regimens commonly used in practice.
- Biologic subtypes are classified by differential expression of transcription regulators, such as ASCL1 (achaete-scute homolog 1), NEUROD1 (neurogenic differentiation factor 1), and POU2F3 (POU class 2 homeobox 3), or low expression of all three transcription factor signatures accompanied by an inflamed gene signature and may have therapeutic implications.
- Combined PD-L1 inhibitors and platinum-doublet chemotherapy improve overall survival in all patients with extensive-stage SCLC and may preferentially benefit patients with the SCLC-I subtype.
- Bispecific T-cell engagers and chimeric antigen receptor T cells designed against unique SCLC tumor antigens, such as DLL3, are novel immunotherapeutic strategies to overcome deficiencies in antigen presentation, which are common in SCLC.

UNRAVELING THE BIOLOGY AND MOLECULAR FEATURES OF LUNG NENS

Molecular Features of Lung NETs (pulmonary carcinoids)

Unlike lung NECs (SCLC and LCNEC), NETs present with a low mutational rate, frequent alterations in chromatin-remodeling genes, and rare mutations in *TP53* and *RB1*.[4-7] *MEN1*, *EIF1AX*, and *ARID1A* are significantly mutated genes, with 5% of patients affected by MEN1 syndrome.[8,9] Although lung NETs are considered as a single entity, a recent multiomic study by Alcala et al[10] suggests that these tumors comprise three distinct molecular groups (Fig 1). Carcinoid A1 tumors have high levels of *ASCL1* and *DLL3* and enrichment for *EIF1AX* mutations. Carcinoid A2 tumors have low levels of *SLIT1* and *ROBO1*. More than 80% of patients with A1 and A2 tumors are alive >10 years. Carcinoid B tumors have high levels of UGT and CYP genes, *ANGPTL3*, and *ERBB4* and low levels of *OTP* and *TTF1*. These tumors are also enriched for *MEN1* alterations. Only 60% of patients with carcinoid B tumors survive >10 years. These molecular subtypes do not strictly correlate with the morphological classification, although enrichment for typical (A1 and A2) and atypical (B) carcinoids was observed. The existence of these molecular groups was confirmed in an independent series.[11-13]

A recent single-cell study has shown that lung NETs are characterized by an immune microenvironment of noninflammatory monocyte-derived myeloid cells, and a stromal microenvironment constituted of vascular cells and CAF-like myofibroblasts.[14] This study also showed that the abovementioned molecular clusters are not driven by immune or stromal cells, but rather represent tumor intrinsic features. However, they seem to be associated with enrichment for distinct tumor microenvironment cell types, such as monocytes, in cluster B and dendritic cells in cluster A1.

The molecular findings have not yet translated into novel therapeutic options. Currently, only everolimus (a mammalian target of rapamycin inhibitor) has been approved by the US Food and Drug Administration and European Medicines Agency for advanced, progressing, nonfunctional, pulmonary, and digestive NETs (approved in 2016).[15]

Evidence for Novel Morphological Variants and Biological Entities

According to the thoracic WHO classification, lung NETs are divided into grade 1 typical carcinoids and grade 2 ACs.[1] This grading in the lung is based on the mitotic count, with a maximum of 10 counts per 2 mm^2 for ACs. Beyond this ceiling, lung NENs are by default classified as LCNECs. However, recent findings suggest the existence of additional entities that might not completely fit into the current classification (Fig 1). Understanding the implications of these new entities is crucial because the distinction between lung NETs and NECs determines the most appropriate clinical management: Surgical resection is the standard for localized tumors, mostly NETs, while chemoimmunotherapy is preferred for advanced NECs.

The grade 3 lung NETs, a highly proliferative emerging variant. Despite the abovementioned criteria, there have been several reports of lung NENs with classically carcinoid morphology (bland, uniform cytology, and absence/focal necrosis) but higher mitotic counts (>10/2 mm^2).[16-20] These NENs also present with higher Ki67 levels than expected for lung NETs (>30%), a marker of proliferation. The presence of *MEN1* mutations and the absence of *RB1* and *TP53* alterations further support their relationship with carcinoids. However, these tumors appear to be highly aggressive, showing higher rates of postsurgical recurrence, as compared with the recurrence rate for conventional ACs (approximately 20-30%). Interestingly, in the digestive system, a similar subgroup of highly proliferative yet well-differentiated NET has been recently recognized, named

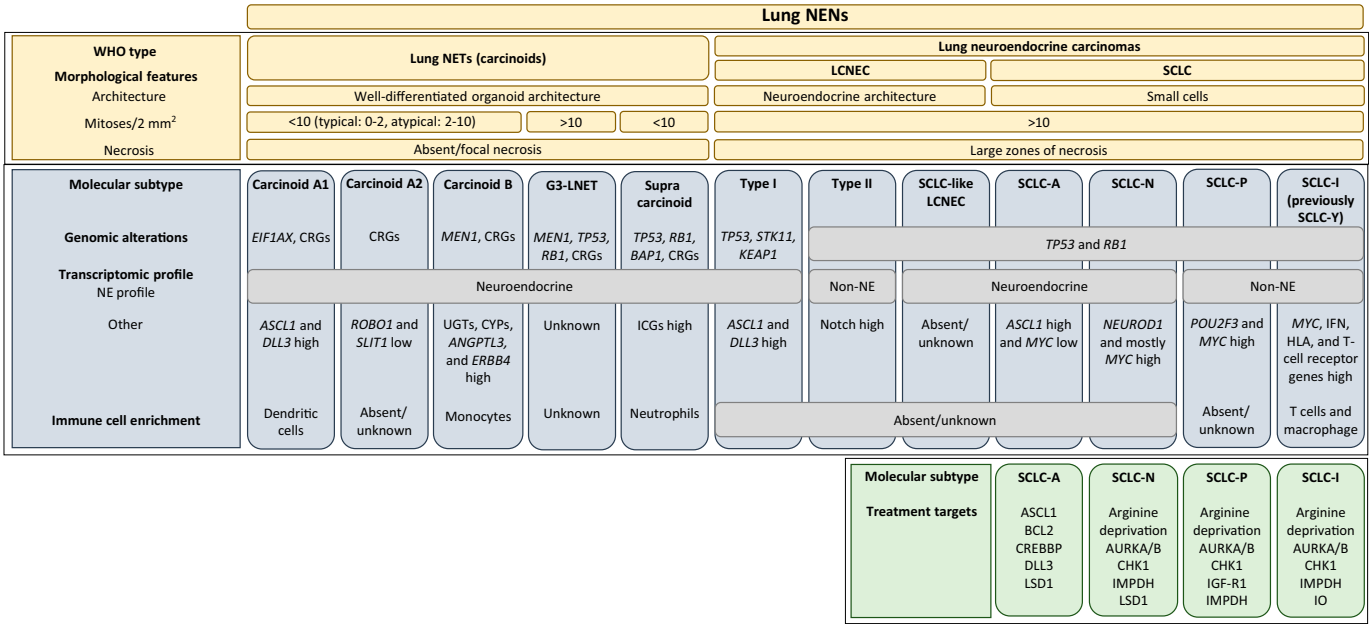

FIG 1. Morphological molecular spectrum of lung NENs. The current classification of lung NE neoplasms, subdivided into tumors (typical and atypical carcinoids) and carcinomas (LCNEC and SCLC) is depicted in orange. Diagnostic morphological features areas are described in the WHO Classification of Tumours.[1] Molecular subtypes of each WHO type are described in blue, including characteristic genomic alterations and gene expression profiles, NE profile (on the basis of whole-transcriptome analyses or immunohistochemsistry of characteristic NE markers), and immune cell enrichment.[6,10-13,16-20,43,46] Treatment targets for SCLC subtypes are depicted in teal.[39] SCLC-I (previously SCLC-Y) may also be known as *ASCL1*/*NEUROD1*/*POU2F3*-negative SCLC. Note, G3-LNET (grade 3 lung NET), and supracarcinoids are emerging morphological and biological entities, respectively, with uncertain economic alterations because of low numbers; CRGs, chromatin remodeling genes; ICGs, immune checkpoint genes; IO, immuno-oncology; LCNEC, large-cell neuroendocrine carcinoma; NE, neuroendocrine; NEN, neuroendocrine neoplasm; NET, neuroendocrine tumor; SCLC, small-cell lung carcinoma.

well-differentiated NETs of grade 3.[21,22] In contrast, in the lung setting, they are classified as LCNEC with morphologic features of carcinoid tumor, nomenclature likely to remain until more data for these tumors can be accumulated.[23]

Supracarcinoids, an emerging biological entity. Although the mitotic count for typical carcinoids and ACs separates two grades of the same disease entity, it is strongly believed that lung NETs and NECs are biologically separate entities on the basis of the distinct genomic profiles found in molecular studies.[24] Surprisingly, Alcala et al[10] identified six samples morphologically classified as ACs that fell into the molecular cluster of LCNEC. They were named supracarcinoids. Supracarcinoids also displayed poor survival (10-year overall survival [OS] of 33%), similar to LCNEC, and a particular immune pattern of high levels of immune checkpoint receptors and ligands and high neutrophil content. These features may represent potential diagnostic and therapeutic candidates for this group of aggressive lung NETs. Simbolo et al[11] also identified four ACs that fell into clusters enriched for LCNECs, supporting the existence of supracarcinoids. The discovery of supracarcinoids suggests that the molecular link between lung NETs and NECs, especially between ACs and LCNECs, might be subtler than initially believed.[25] In line with this, the work of Pelosi et al[26,27] supported the possibility of progression or transition from lung NET to NEC in both the lung and the thymus. In agreement with this idea, a recent study revealed that well-differentiated insulinoma tumors could dedifferentiate and acquire a progenitor-like molecular phenotype, resulting in the development of invasive metastasis-like primary pancreatic NETs. These data demonstrate that dedifferentiation is a mechanistically and temporally separable step in the multistage tumorigenesis of pancreatic islet cells.[28]

Whether grade 3 NETs and supracarcinoids are indeed the same variant discovered through different approaches and what are the implications of their existence for the clinical management of the patients would require designed-for-purpose follow-up studies in larger series.

LCNECs

Molecular studies have shown the existence of two major groups of LCNECs.[6,16,29] The first, named type I LCNEC, displays a NSCLC-like genomic profile (mutations in *STK11*, *KEAP1*, *KRAS*, and other RAS pathway gene alterations) and a NE transcriptomic profile (*ASCL1*-high/*DLL3*-high/*Notch*-low). The second, named type II LCNEC, carries an SCLC-like genomic profile (*TP53* and *RB1* mutations) and a non-NE transcriptomic profile (*ASCL1*-low/*DLL3*-low/*Notch*-high).

A small subset of LCNECs presented with both the genomic (*TP53* and *RB1* mutations) and transcriptomic profiles of SCLC being therefore considered as SCLC-like. These data suggest that LCNEC represents a distinct entity that harbors a unique combination of genomic and transcriptional programs (Fig 1). On the basis of this, LCNEC may indeed be the result of phenotypic convergence of tumor groups derived from distinct cells of origin.[6,16,29] This translates in a vast heterogeneity of LCNEC at both molecular and histological levels. Indeed, combined LCNECs account for 20%-25% of resected LCNECs.[30] Although any non-NE NSCLC histological type may be present, the most frequent co-occurrence is with adenocarcinoma. Genomic studies show that LCNEC and NSCLC components are clonally related, supporting the concept of phenotypic divergence rather than a collision phenomenon.[29]

The optimal systemic treatment for patients with stage IV LCNEC is yet to be defined, with both SCLC and NSCLC chemotherapy regimens commonly used in practice.[31] Of note, given the rare tumor type, clinical trials tailored for patients with LCNEC are lacking, especially in the era of immunotherapy.[32] The abovementioned molecular findings encouraged further retrospective studies that found differences in prognosis and therapeutic outcomes to SCLC-like and NSCLC-like chemotherapy regimens of patients on the basis of the molecular subtype of their LCNEC tumor. However, these studies showed contradictory findings, and the global response to chemotherapy was generally quite poor.[33,34] These findings highlight the unmet need to find novel therapeutic options for these patients.[15,35] An example of such therapeutic options includes the effective targeted agent sotorasib against LCNEC harboring *KRAS G12C* mutations.[36] DLL3 targeted therapy may represent another promising opportunity for stage IV LCNEC, given the high percentage (74%) of *DLL3* expression in these advanced tumors.[37]

SCLC

SCLC was once defined as a homogeneous disease marked by mutational alterations associated with tobacco-related carcinogenesis; however, this has evolved with discovery of morphologic, epigenetic, and transcriptomic heterogeneity. DNA sequencing data demonstrate a high tumor mutation burden,[4,38] with near universal loss of the tumor suppressor genes *TP53* and *RB1*.[5] In preclinical studies, loss of function of TP53, RB1, and NOTCH lock NE progenitors into a self-renewal program and thereby contribute to tumorigenesis and transformation to SCLC.[39] Most recent studies have revealed distinct subsets such as the identification of subsets of MYC-driven SCLC,[40-42] with metabolic heterogeneity that suggested arginine deprivation as a potential therapeutic vulnerability for MYC-driven SCLC. Further work has led to the classification of transcription factor–defined subsets that include the subtypes SCLC-A, SCLC-N, SCLC-P, and SCLC-Y, defined by increased expression of achaete-scute homolog 1 (*ASCL1*), neurogenic differentiation factor 1 (*NEUROD1*), POU class 2 homeobox 3 (*POU2F3*), or low expression of all three transcription factor signatures accompanied by an inflamed gene signature, respectively.[43]

SCLC-A is the dominant subtype, with high expression of NE markers including chromogranin A and synaptophysin.[44] The SCLC-N subtype was previously referred to as the variant type with more loosely aggregated cells and decreased expression of NE markers. Numerous other genes are differentially regulated among these two subtypes, including high *MYCL*, *BCL2*, *SOX2*, and *DLL3* in SCLC-A and high *MYC*, *INSM1*, and *HES6* in SCLC-N. SCLC-P was identified as defining a previously unappreciated non-NE, tuft-cell variant of SCLC.[45] The fourth subtype driven by the transcription factor YAP1 proposed a partial solution to these unclassified tumors and has been shown to correlate with high expression of interferon-γ response genes, a T-cell–inflamed phenotype, and high expression of HLA and T-cell receptor genes.[46] However, YAP1 protein expression as measured by immunohistochemistry was more variable and did not distinctly identify this subtype.[47] It is now also referred to as SCLC-I for *ASCL1*/*NEUROD1*/*POU2F3*-negative profile with an inflamed gene signature.[43] Recent studies have called into question whether these represent separate subtypes altogether, and further classification is ongoing.[43,47]

In addition, for the complexity of the heterogeneity of these SCLC tumors, studies have shown not only intertumoral heterogeneity but also intratumoral heterogeneity and how this may influence development of chemoresistance in preclinical models. These subtypes are fluid, and more than one transcriptional subtype may exist within a tumor or shifts in subtypes may occur during therapy as a potential driver of chemoresistance.[43,48-50] To highlight this, these subtypes may not be static but are driven from a pulmonary neuroendocrine cell of origin to the classic *ASCL1*+, *NEUROD1*+, and then *YAP1*+ subtype by dynamic changes in notch signaling driven by MYC.[49] Several studies demonstrated that MYC expression and the non-NE SCLC phenotype increase after chemotherapy treatment while NE identity decreases. This has been associated with development of resistance to chemotherapy with platinum and etoposide.[51] In addition, SCLC-A can evolve to a different subtype, such as SCLC-N or SCLC-Y.[49] The mechanisms underlying or leading to plasticity are under investigation.

Real-world multiomic characterization of SCLC subtypes using comprehensive molecular profiling was performed in 437 samples from patients with SCLC and high-grade NE lung carcinomas. In this study, tumors were categorized into

five subgroups (SCLC-A/N/P/Y and SCLC-mixed) on the basis of the relative expression of the four transcription factors, resulting in 35.7% of SCLC-A, 17.6% of SCLC-N, 6.4% of SCLC-P, 21.1% of SCLC-Y, and 19.2% of SCLC-mixed samples. SCLC-Y was associated with the highest expression of T-cell inflamed, NK cell, and STING pathway signatures.[52]

Given the challenges in obtaining tissue biopsies in patients with SCLC, utilization of cell-free DNA to assess the methylation profile of SCLC[53] has emerged as a promising tool in subtyping and disease monitoring, including facilitating analyses of plasticity and interconversion between subtypes as a mechanism of acquired resistance. Machine learning determined 366 differentially methylated regions and was validated on patient-derived xenograph samples. In a cohort of 56 cell-free SCLC DNA samples, 3% were classified as *ASCL1*+, 13% were classified as *NEUROD1*+, and 14% were classified as being double negative. Methylation scores of high versus low were applied to patient samples on the basis of median cutoff, and patients with low scores had significantly longer median OS than patients with high scores (20.6 *v* 8.5 months, two-sided log-rank test, $P = .00015$).[53]

More recently, characterization of the tumor immune microenvironment (TIME) among transcriptomic subtypes of SCLC provided insight into patient selection for immune checkpoint inhibitors.[54,55] Using matched SCLC tumor samples from endobronchial ultrasound transbronchial needle aspirates and peripheral blood mononuclear cells (PBMCs), Best et al[54] found distinct immune checkpoint and cytotoxic signature profiles within each transcriptomic subtype of SCLC. SCLC-N had the lowest expression of immune-related genes, whereas SCLC-P had the highest. A range of immune-related gene expression was observed across SCLC-A tumors. These findings were recapitulated in a second study, which demonstrated a statistically significant association of SCLC-N and an immune cold phenotype.[55] Furthermore, the TIME of SCLC-N had more Tregs and fewer CD8+ T cells compared with other subtypes.[55]

CURRENT STATUS OF THERAPEUTIC INTERVENTIONS: A FOCUS ON SCLC

In recent years, several therapeutic advances have been made in NE tumors. An in-depth discussion on therapies for NENs is beyond the scope of this study. In this section, we focus on the evolving treatment landscape and exciting developments of immunotherapies in SCLC.

SCLCs are characterized by rapid tumor growth and early metastatic spread for which systemic therapy is necessary for all stages of disease. A summary of studies involving immune checkpoint inhibitors, including both positive and negative studies, is provided in Table 1. Clinical studies of single-agent PD-1 and PD-L1 inhibitors in relapsed/refractory SCLC had disappointing results with low response rates and no improvements in survival.[56-58] It appears that PD-L1 inhibitors need to be given in combination for SCLC. The addition of PD-L1 inhibitors to platinum-doublet chemotherapy demonstrated improvements in survival of patients with extensive-stage (ES) SCLC in several studies, which is currently the standard first-line therapy.[59,60-65] The IMpower133 study is a phase III study randomly assigning patients with ES-SCLC to chemotherapy with or without the PD-L1 inhibitor, atezolizumab.[59] Patients receiving atezolizumab and chemotherapy had a statistically significant improvement in OS of 12.3 months compared with 10.3 months in patients receiving chemotherapy alone (hazard ratio [HR], 0.70; 95% CI, 0.52 to 0.91). The CASPIAN study, which investigated chemotherapy with or without durvalumab, demonstrated similar improvements in survival (median OS 13.0 *v* 10.3 months; HR, 0.73; 95% CI, 0.59 to 0.91).[61] Interestingly, the addition of pembrolizumab demonstrated only statistically significant improvement in progression-free survival, but not OS.[62] The negative result of this study was felt to be related to complexity of the statistical design and overperformance of the control group. The benefits of PD-L1 inhibitors were generally thought to be a class effect.[59,61--65] Despite this milestone achievement, the absolute benefit of PD-L1 inhibitors was modest.

Efforts to combine checkpoint inhibitors to improve outcomes were met with disappointing results (Table 1). The CASPIAN study included a group that was treated with chemotherapy, durvalumab and tremelimumab, a cytotoxic T-lymphocyte–associated protein-4 checkpoint inhibitor.[61,66] Unfortunately, patients receiving the quadruplet derived no statistically significant benefit compared with chemotherapy alone (HR, 0.82; 95% CI, 0.68 to 1.00). Similarly, the combination of ipilimumab and nivolumab failed to demonstrate any improvement in survival when used as maintenance therapy or in patients with relapsed/refractory SCLC.[67,56] Efforts at combining PD-1 inhibition with another coinhibitory checkpoint, T-cell immunoglobulin and ITIM domain (TIGIT), also failed. Despite correlative data showing high polio virus receptor expression on SCLC, a natural ligand to TIGIT, the phase III SKYSCRAPER-02 study failed to improve survival over standard therapy (HR, 1.04; 95% CI, 0.79 to 1.36).[68]

The use of poly ADP-ribose polymerase (PARP) inhibitors was hypothesized to increase tumor immunity through DNA damage–induced innate immunity.[69] Unfortunately, clinical trials of combined PARP and PD-L1 inhibition failed to improve responses in previously treated SCLC (Table 1).[70,71] In a phase II study of relapsed/refractory SCLC, treatment with olaparib and durvalumab had an overall response rate (ORR) of 10.5%.[70] However, treatment with PD-L1

TABLE 1. Clinical Studies of PD-L1 Checkpoint Inhibitors in Small-Cell Lung Cancer

Abbreviations: EMA, European Medicines Agency; FDA, US Food and Drug Administration; HR, hazard ratio; OS, overall survival; PFS, progression-free survival; SCLC, small-cell lung carcinoma.

[a]Chemotherapy refers to a standard platinum doublet with cisplatin/carboplatin and etoposide.

[b]Where a *P* value is not reported, statistical significance was not formally tested in the clinical study.

[c]*P* value does not meet predefined threshold of statistical significance.

[d]Chemotherapy refers to oral or intravenous topotecan or amrubicin.

inhibitors alone is known to have low response rates in the relapsed/refractory setting. Ongoing studies will further investigate the potential for PARP inhibitors in earlier line settings and in combination with radiation or temozolomide, which appeared synergistic, independent of PD-L1 inhibition (ClinicalTrials.gov identifiers: NCT04728230, NCT03830918). Mutations in *SLFN11* were recently identified as a biomarker of response to PARP inhibitors and may refine patient selection.[72,73]

An agent that has demonstrated preliminary efficacy in combination with nivolumab is the ganglioside fucosyl-GM1 antibody BMS-986012. In a phase I/II study of BMS-986012 with or without nivolumab, the combination demonstrated synergistic effect with an objective response rate of 38% in

previously treated SCLC (Table 1).[74] Although the mechanism of synergy remains elusive, the combination is being further investigated in a first-line randomized phase II clinical study (ClinicalTrials.gov identifier: NCT04702880).

Despite the modest benefits of immune checkpoint inhibitors in SCLC, a subset of patients appeared to derive durable benefits. In the IMpower133and CASPIAN studies, the 2-year OS rate is almost doubled in the immunotherapy group.[59,60,61,75] The 3-year OS rate in the CASPIAN study was an impressive 17.6%.[75] Furthermore, in the pooled analysis of the KEYNOTE-028 and KEYNOTE-158 studies in which patients with relapsed/refractory SCLC were treated with pembrolizumab, the subset of responders had a remarkable duration of response ranging from 4.1 to >36 months.[58] Thus, characterization of the tumor and host immune interactions is necessary for successful development of immunotherapeutic approaches in SCLC.

Lack of Predictive Biomarkers and the Tumor Immune Microenvironment

SCLC is a particularly immune cold cancer.[76-78] Transcriptomic analysis of human SCLC samples demonstrated a particularly low CD45+ T-cell infiltration compared with lung adenocarcinomas. Furthermore, the TIME of SCLC was enriched for immunosuppressive monocytes and macrophages.[55] In retrospective studies, the only factor that demonstrated a positive association with response was CD8+ T-cell infiltration.[79-83] These observations partly explain the limited benefits of PD-L1 inhibitors in SCLC and the poor correlation with known biomarkers in other cancer types.

The incidence of PD-L1 expression is low in SCLC. In the biomarker analysis of the IMpower133 study, 53% of patients had PD-L1 expression ≥1%, but only 21% had PD-L1 expression ≥5% on tumor or immune cells.[60] There was no association between PD-L1 expression, response, and survival. Similarly, high tumor mutational burden, which associates with response across several different tumor types, did not confer any advantage in SCLC.[60]

To understand the clinical relevance of SCLC subtypes as a way to refine patient selection, an exploratory analysis was conducted using data from the IMpower133 study. Interestingly, similar trends toward the benefit of atezolizumab plus chemotherapy were observed across all subtypes, including the immune cold SCLC-N subtype.[43] Instead, a fourth subtype, SCLC-I (*ASCL1*, *NEUROD1*, and *POU2F3* low), benefitted preferentially from the addition of atezolizumab.[43] Among 49 patients with SCLC-I subtype, the median OS for those receiving atezolizumab plus chemotherapy compared with chemotherapy alone was 18 and 10 months, respectively (HR, 0.56). Using a similar method of classification, exploratory analysis of the CASPIAN study demonstrated strikingly similar results.[84] Patients with the SCLC-I subtype had a median OS of 17.6 months with durvalumab plus chemotherapy compared with 11.3 months with chemotherapy alone.[84] Corresponding to improved survival, gene expression profiling using an 18-gene panel also demonstrated the expression of inflamed T-cell markers in the SCLC-I subtype.[43,84]

Future Developments in Immunotherapeutics

The heterogeneity in TIME of SCLC suggests that a more selective approach is needed for successful drug development. Ongoing studies involve combinations of PD-L1 inhibitors that have demonstrated efficacy in other tumor types. For example, combined PD-L1 and vascular endothelial growth factor inhibitors, effective in hepatocellular carcinomas and renal cell carcinomas, is thought to be synergistic through modulation of myeloid-related immunosuppression.[85-87] Other studies investigate the role of PARP and ataxia telangiectasis and rad-3 related inhibitors in potentiating the effect of PD-L1 inhibitors through DNA damage–induced immunity.[69] Other novel immunotherapies under active investigation for SCLC are summarized in Table 2.

Defective major histocompatibility complex 1 (MHC) antigen presentation is an emerging hypothesis of resistance to immunotherapy in SCLC. Mutations in *β2 microglobulin*, a component of MHC-I, and transcriptional suppression of MHC-I were described as a mechanism of acquired resistance to checkpoint inhibitors in Merkel cell carcinomas and melanoma.[88,89] In SCLC, comparative analysis of gene expression profile of surgically resected SCLC demonstrated that expression of genes related to tumor immunity, such as MHC, *β2 microglobulin*, and *CXCL9*, was associated with long-term survival of longer than 4 years.[80]

Epigenetic therapy may reverse deficiencies in antigen presentation by modulating large areas of transcription programs. In preclinical studies, polycomb repressive complex 2 (PRC2) was found to have a key role in direct repression of MHC-I antigen presentation.[90] Inhibition of PRC2 by inhibiting enhancer of zeste homolog 2 (EZH2), its catalytic component, restored cell surface MHC-I expression. In genetically engineered mouse models, treatment with EZH inhibitors was associated with induction of MHC-I transcription, proinflammatory cytokine production, and T-cell activation.[90] EZH inhibitors are currently investigated as monotherapy or in combination with immunotherapy in SCLC.

T-cell engagers and chimeric antigen receptor T-cell (CAR-T) therapy are novel approaches in overcoming defective MHC antigen presentation.[91] The binding of tumor antigen and CD3 by a T-cell engager creates a cytolytic synapse that allows T-cell activation without MHC-dependent antigen presentation. The tumor antigen delta-like ligand 3 (DLL3) is an attractive therapeutic target

TABLE 2. Active Clinical Trials Investigating New Immunotherapies for Small-Cell Lung Carcinoma

Trial	Investigational Drug	Phase	Line	End Point
PD-1 and VEGF inhibitors				
NCT05384015	Pembrolizumab, lenvatinib, chemotherapy	II	First line	Safety PFS
PD-1 and PARP inhibitors				
NCT03958045	Rucaparib, nivolumab	II	First line	PFS
NCT04624204	Pembrolizumab, olaparib	III	Limited stage	PFS OS
NCT04728230	Olaparib, durvalumab, chemotherapy, radiation	I/II	First line	Safety
NCT03830918	Niraparib, atezolizumab, temozolomide	I/II	≥second line	Safety PFS
PD-1 and ATR inhibitors				
NCT04699838	Ceralasertib, durvalumab, chemotherapy	II	First line	PFS
PD-1 and fucosyl-GM1 antibody				
NCT04702880	BMS-986012, nivolumab, chemotherapy	III	First line	PFS
EZH2 inhibitors				
NCT05353439	Tazemetostat, pembrolizumab, topotecan	I	≥second line	Safety
NCT03460977	PF-06821497	I	≥second line	Safety
DLL3 T-cell engagers				
NCT05060016	Tarlatumab	I	≥second line	ORR
NCT05361395	Tarlatumab, atezolizumab/durvalumab, chemotherapy	Ib	First line	Safety
NCT05619744	RO7616789	I	≥second line	Safety
NCT04429087	BI764532	I	≥second line	Safety
NCT04471727	HPN328	I/II	≥second line	Safety
DLL3 CAR-T				
NCT05680922	LB2102	I	≥second line	Safety
Innate/NK cell–targeting therapies				
NCT04101357	BNT411 (TLR7 agonist), atezolizumab, chemotherapy	I/II	First line	Safety
NCT05652686	PT217	I	≥second line	Safety

Abbreviations: ATR, ataxia telangiectasis and rad-3 related; CAR-T, chimeric antigen receptor T-cell; NT, natural killer; ORR, overall response rate; OS, overall survival; PARP, poly ADP-ribose polymerase; PFS, progression-free survival; VEGF, vascular endothelial growth factor.

in SCLC.[92] DLL3 is expressed in >80% of SCLC but uncommonly expressed in normal cells, thus minimizing the potential for toxicity.[92] Tarlatamab is a DLL3 bispecific T-cell engager that is being actively investigated in clinical studies. In the phase I dose escalation study of tarlatamab, 64 patients with previously treated SCLC had a confirmed partial response rate of 13% across all dose levels and a disease control rate of 43%.[93] HPN328, a trispecific DLL3 T-cell engager that binds DLL3, CD3ε, and albumin, also reported positive preliminary results.[94] In nine patients with previously treated SCLC, the ORR across dose levels to HN328 was 33%. A highly promising therapeutic approach and several other DLL3-targeting T-cell engager therapies are under investigation (Table 2).

The innate immune system also plays an important role in immune surveillance and may be particularly important in tumors with downregulated MHC.[95] In a study using matched SCLC tissue and PBMCs, natural killer (NK) cell infiltration was found to be significantly reduced in the tumor. Furthermore, in mouse studies, depletion of NK cells, but not CD8+ T cells, resulted in increased SCLC dissemination to the liver and lungs.[54] Therapeutics strategies to target the innate immune system include toll-like receptor (TLR) agonists, stimulator of interferon gene (STING) agonists, cytokines, engineered monoclonal antibodies with preferential Fcγ receptor binding to enhance antibody-dependent cellular cytotoxicity (ADCC), and CAR-NK therapy.[95] Although early in development, therapies

aimed at enhancing NK cell immunity may become important for SCLC in the future.

CONCLUSION

The increasing role of gene expression profiling in lung NEN studies is particularly striking. In carcinoids, it has led to the discovery of three distinct molecular subtypes with prognostic values and supracarcinoids.[10] In LCNEC, NE and non-NE transcriptomic profiles have been identified, also associated with specific genomic alterations.[6,16] Finally, although SCLC genomic profiles are quite homogeneous, the high transcriptomic diversity has translated into four molecular subtypes defined by the relative expression of three key transcription regulators.[43,47,62]

Identifying biologically homogeneous tumor subtypes is appealing, as one might expect more similar clinical course and response to therapy, and one valuable methodology to uncover such phenotypes is the average gene expression over all cells in the tumor (including the tumor microenvironment). In this regard, the multitask evolution of cancer theory is a powerful framework to describe, using gene expression data, how tumors evolve and face selection tradeoffs between biological functions.[96] Tumors that specialize in a particular task could be more sensitive to drugs that impair that task, and actionable driver mutations may also tune gene expression levels toward specialization in specific tasks. Together, these analyses can generate hypotheses around the therapeutic vulnerabilities of these emerging lung NEN subtypes,[96] which should help to concentrate and speed up therapeutic research, eventually producing biologically based targeted treatments that could improve clinical outcomes for patients with these rare diseases.

In parallel with advances in understanding the molecular biology of lung NENs, developments in immunotherapeutics have improved outcomes in patients. The combination of PD-L1 inhibitors and chemotherapy improves survival in SCLC across clinical studies, a first advancement in many decades for this disease. Research for predictive biomarkers is ongoing and will guide design of rationale combinations build upon the backbone of chemo-immunotherapy. The identification of molecular subtypes has led to enthusiasm in the field since exploratory studies suggest correlation with clinical outcomes. Further refinement in subclassifications may assist in selecting patients for clinical trials. Finally, better characterization of the tumor-host immune interactions can lead to the development of novel therapeutic strategies for lung NENs.

LUNG CANCER

Treatment Decisions for Resectable Non–Small-Cell Lung Cancer: Balancing Less With More?

David O'Reilly, MBBCh, BAO, MSc, MRCPI[1,2]; Angela Botticella, MD[3]; Simon Barry, MBBCh, BAO, MSc[1]; Seamus Cotter, BSc[4]; Jessica S. Donington, MD, MSCR[5]; Cecile Le Pechoux, MD[3]; and Jarushka Naidoo, MBBCh, BAO, MHS[1,6]

Overview

For patients with non–small-cell lung cancer (NSCLC), the outcomes for patients with resectable disease are historically poor compared with other solid organ malignancies. In recent years, there have been significant advances in multidisciplinary care, which have resulted in improved outcomes. Innovations in surgical oncology include the use of limited resection and minimally invasive techniques. Recent data in radiation oncology have suggested refinements in pre- and postoperative radiation therapy, resulting in optimization of techniques in the curative setting. Finally, the success of immune checkpoint inhibitors and targeted therapies in the advanced setting has paved the way for inclusion in the adjuvant and neoadjuvant settings, resulting in recent regulatory approvals for four regimens (CheckMate-816, IMpower010, PEARLS, ADAURA). In this review, we will provide an overview of the seminal studies informing advancements in optimal surgical resection, radiation treatment, and systemic therapy for resectable NSCLC. We will summarize the key data on survival outcomes, biomarker analyses, and future directions for perioperative studies.

INTRODUCTION

Non–small-cell lung cancer (NSCLC) is the leading cause of cancer-related mortality worldwide, with an estimated 1.8 million lung cancer deaths in 2020.[1] Unfortunately, most patients (60%-70%) present with late-stage disease and treatment is not delivered with curative intent.[2] However, even for patients with early-stage disease, NSCLC poses a significant clinical challenge with a propensity for distant metastasis and early relapse.[3] Given the high risk of relapse for patients with resectable NSCLC, improving the outcomes for these patients has been a focus of multidisciplinary research in recent years.

The early-stage NSCLC space is separating into two populations, with distinct clinical and research questions. In very early-stage disease (stage IA1-IA2), the questions center around the extent of resection and the ability to do less without compromising oncologic outcomes. In patients with stage IB-IIIA disease, there is a far greater risk for recurrence and although surgery remains central to treatment, the approach is multimodality and the questions focus on how to safely combine systemic therapy, radiation, and surgery together for greatest benefit. Pivotal trials have investigated the role of postoperative radiation therapy (PORT) in patients with high-risk resected NSCLC. Defining the population that may benefit from PORT while minimizing cardiopulmonary toxicity remains a challenge. Immune checkpoint inhibitors (ICIs), targeting PD-1, PD-L1, or cytotoxic T-cell lymphocyte (CTLA)-4, have transformed outcomes for advanced solid organ malignancies particularly in diseases such as melanoma, NSCLC, and renal cell carcinoma.[4] This has resulted in long-term survival (>5 years) for a subset of patients with these malignancies. More recently, there have been studies investigating the use of ICIs in early-stage NSCLC (adjuvant or neoadjuvant), with the goal of improving the current limited benefits of perioperative systemic chemotherapy.

Herein, we will summarize the current standard of care in the perioperative management of resectable NSCLC. We will review the most recent evidence exploring optimal surgical resection, radiation therapy (RT), and the use of neoadjuvant and adjuvant systemic therapies in resectable NSCLC.

RESECTION OF LOCALIZED LUNG CANCER

Jessica S. Donington, MD, MSCR, Professor of Surgery and Chief Section of Thoracic Surgery, University of Chicago Medicine and Biologic Sciences

New evidence on the extent of resection. Lobectomy was the gold standard for treatment of all early-stage tumors since the 1995 publication by the Lung Cancer Study Group (LCSG) of their randomized trial comparing lobectomy with limited resection for stage I NSCLC. This trial demonstrated a significant increase in local

PRACTICAL IMPLICATIONS

- Recent progress in the management of patients with resectable non–small-cell lung cancer (NSCLC) has resulted in improved outcomes.
- Sublobar resection is now a recognized standard of care for patients with stage 1A1 or 1A2 resectable NSCLC.
- Postoperative radiation therapy is associated with significant cardiopulmonary toxicity and is reserved for patients with high-risk features (eg, R1 or R2 resection).
- Adjuvant and neoadjuvant systemic therapy has evolved to now include immune checkpoint inhibitors and targeted therapies with approval of four regimens (CheckMate-816, IMpower010, PEARLS, and ADAURA).

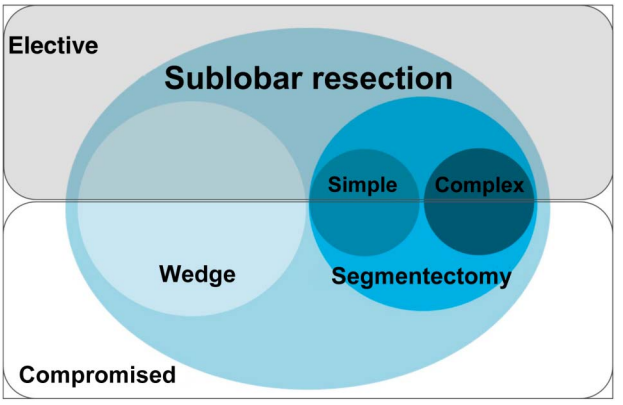

FIG 1. Surgical resection in non–small-cell lung cancer. Sublobar resections include wedge or segmentectomy (simple or complex), elective procedures in those with adequate physiologic reserve, and compromise procedure in those who could not tolerate lobectomy.

recurrence with sublobar resection and set the standard in surgical care for early-stage NSCLC for 25 years.[5] The trial is now felt to represent a different era with limited staging technology, and the results may not be fully applicable today. The landmark LCSG trial completed accrual in the 1980s before the full integration of computed tomography (CT) scans or F-labeled fluorodeoxyglucose (FDG)-positron emission tomography (PET) into NSCLC staging, and neither was required for enrollment. The increased accuracy and availability of cross-sectional imaging and added staging precision with FDG-PET have rekindled interest in sublobar resections. These advances also coincide with better understanding of the heterogeneity of biology in early-stage disease and the full spectrum of adenocarcinoma subtyping.[6]

Over the past 2 decades, numerous large database studies, single-institutional retrospective studies, and meta-analyses have demonstrated equivalency of oncologic outcomes of sublobar resection compared with lobectomy for select patients with stage IA NSCLC[7-9] and suggested the importance of tumor size, grade, and histologic subclassification when deciding between a sublobar resection and lobectomy.[10,11] Unfortunately, retrospective work in this arena is challenging since the decision between procedures can be affected by patient comorbidity. Sublobar resection can be used as an elective procedure in patients with adequate physiologic reserve for lobectomy or as a compromise procedure in patients who could not tolerate lobectomy. Most large databases do not include pulmonary function data or information on surgical intent. Adding to the challenge is the fact that sublobar resection is an umbrella term that includes segmentectomy and wedge and now segmentectomy can be broken down into simple and complex segmentectomy (Fig 1).

Two large prospective randomized trials comparing lobectomy with sublobar resection for stage IA NSCLC reported results in the past 2 years and will guide surgical care for early-stage care for decades to come. Each trial required CT and FDG-PET for staging and limited tumor size to <2 cm, smaller than the 3-cm size limit for the LCSG trial.

JCOG0802/WJOG4607. The Japanese trial, JCOG0802/WJOG4607, randomly assigned 1,106 patients between lobectomy and segmentectomy (wedge resections were not allowed) and noted equivalent short-term surgical outcomes between procedures with no differences in surgical approach, length of procedure, blood loss, hospital stay, morbidity, or mortality.[12] The primary outcome, 5-year overall survival (OS), was superior in the segmentectomy arm (hazard ratio [HR], 0.663; 95% CI, 0.47 to 0.92), and a trend toward improved survival was noted in all subgroups evaluated.[13] Surprisingly, the difference in pulmonary function tests at 1-year postoperative were smaller than anticipated (–8.5% *v* –12.0%). Local recurrences were more common in the segmentectomy group (6.9% *v* 3.1%), but most were salvageable and did not lead to mortality. The most notable mortality benefit for segmentectomy was related to fewer deaths from other cancers (including second primary lung cancers) and from nonmalignant disease. This suggests an overall health benefit to preserved lung parenchyma.

CALGB/Alliance trial 140503. The trial from North American cooperative group CALGB/Alliance randomly assigned 697 patients to lobectomy or sublobar resection. Sublobar resection could be segmentectomy or wedge resection, a distinct difference from the JCOG0802/WJOG4607 trial. It also noted no differences in short-term perioperative morbidity or mortality between lobectomy and sublobar resection.[14] The primary end point was disease-free survival (DFS), and at a median follow-up of 7 years, no difference was

reported (63.6% *v* 64.1%; HR, 1.01; 95% CI, 0.83 to 1.24) in 2022.[15,16] Similarly, no difference in OS was noted (80.3% *v* 78.9%; HR, 0.95; 95% CI, 0.72 to 1.26). Nearly 60% of the sublobar resections in this trial were wedge resections. Subgroup analysis of outcomes stratified by the type of sublobar resection are expected in the spring of 2023.

Intraoperative lymph node evaluation. One thing that these two trials had in common was the importance placed on complete lymph node evaluation when considering a sublobar resection. Pathologic nodal stage is the most significant prognostic factor in resectable NSCLC. Each of these trials preregistered patients before the day of surgery, but random assignment was performed during the operation, after confirmation of N0 status by means of frozen section evaluation of hilar and mediastinal lymph nodes. This step of frozen section lymph node evaluation before performing a planned sublobar resection is not common in clinical practice and causes some to question the validity of results if this step is not integrated as routine operative care.

Intraoperative nodule localization. The need to precisely localize small nonpalpable lung nodules within segmental boundaries for surgical resection is now a major concern and has driven an explosion in novel localization technologies. These fall into five basic categories: (1) preoperative 3D imaging platforms; (2) intraoperative imaging adjuncts, such as thoracoscopic ultrasound; (3) physical markers, such as hook wires, fiducials, and microcoils; (4) parenchymal dyes or tattoos delivered via a bronchoscope; and (5) molecular targeting agents, which are delivered systemically, collect in the tumor, and can be visualized intraoperatively with fluorescence imaging. Use of these novel techniques is greatly facilitated by hybrid operating rooms that contain cone beam CT, fluoroscopy, and molecular imaging capability. Although early in development, these technologies show promise. Further refinement will broaden their utility and will stimulate advancement of safer and more precise operative techniques.

Conclusion. Care for early-stage NSCLC is becoming more personalized with a more tailored approach to resection. An important aspect of this is the new evidence supporting sublobar resection for well-selected peripheral stage I tumors <2 cm. Appropriate use of sublobar resection places increased importance on operative lymph node evaluation and tumor localization.

ROLE OF RADIATION IN RESECTABLE LUNG CANCER

Cecile Le Pechoux, MD, Senior Radiation Oncologist, Gustave Roussy Campus University Hospital, Villejuif, France

Introduction. Surgical resection is the cornerstone of treatment of all operable early-stage NSCLC, and (neo) adjuvant chemotherapy has been the standard of care in stage IB-IIIA NSCLC for over 20 years.[17,18] However, even with major changes in the therapeutic management of these operable patients, the risk of a recurrence is still high especially in stage III: up to two thirds of them present a relapse and 20% to 40% of those patients present with a locoregional failure.[19]

The role of PORT was evaluated in several trials performed in the 70-90s, all conducted with radiation techniques nowadays considered obsolete, such as Cobalt, in the pre–3D conformal radiotherapy era.[20,21] The PORT meta-analysis, published in 1998, showed a detrimental effect of PORT of 7% on OS at 2 years.[21] Subgroup analyses suggested that this adverse effect was greatest for pN0-N1 patients, whereas for those with pN2 disease, there were possible benefits that needed further evaluation and no clear evidence of an adverse effect.[21] The PORT meta-analysis is felt to represent a different era, with both surgical and radiotherapy techniques having evolved (expanding indications for video-assisted thoracoscopic surgery, widespread use of 3D conformal radiotherapy, in the 2000s) and the preoperative staging dramatically improved with the FDG PET-CT scan and brain imaging.

Despite the low evidence level, PORT continued to be proposed to patients at high risk of locoregional failure: in the case of incomplete resection (R1-R2 disease) or completely resected N2 disease. Its use was supported by several large database studies and a meta-analysis of the PORT phase III trials, suggesting that modern PORT might confer an advantage in OS after adjuvant chemotherapy, possibly because of a lower cardiopulmonary toxicity.[22-27]

Lung ART and PORT-C. Two phase III randomized trials comparing the outcomes of PORT in patients with completely resected stage III N2-positive NSCLC have been recently published: the Lung Adjuvant Radiotherapy Trial (Lung ART) and the PORT-C.[28,29] The multi-institutional European Lung ART trial randomly assigned 501 patients (treated between 2007 and 2018) to PORT after the completion of surgery or surgery and adjuvant chemotherapy (252 patients in the PORT group and 249 patients in the control group).[28] Pretreatment staging included FDG-PET-CT scan in 91% of patients. The majority of patients received pre- and/or postoperative chemotherapy (96%). In the PORT group, 89% had 3D conformal RT and 11% had intensity-modulated radiation therapy (IMRT). At a median follow-up of 4.8 years, there was no significant in DFS between groups (HR, 0.86; 95% CI, 0.68 to 1.08). The median DFS was 30.5 months and 22.8 in the PORT group and in the control group, respectively. The 3-year OS was similar in the two arms (67% in the PORT arm *v* 69% in the control arm). Of the 296 patients with DFS events, 36 (25%) had a mediastinal relapse and 105 (73%) had a distant relapse in the PORT arm versus 70 (46%) and 98 (64.5%) in the control arm, respectively.

The PORT-C trial randomly assigned 364 patients coming from a single center (treated between 2009 and 2017) to PORT after the completion of surgery and adjuvant chemotherapy (184 patients in the PORT group and 180 in the control group).[29] Pretreatment staging details (FDG-PET-CT scan use) were not reported. The majority of patients (89.3%) were treated with IMRT. At a median follow-up of 46 months, according to an intention-to-treat analysis, the median DFS for patients in the PORT arm and observation arm was 22.1 months and 18.6 months, respectively (3-years DFS: 40.5% in the PORT arm *v* 32.7% in the observation arm [HR, 0.84; 95% CI, 0.65 to 1.09]). The median OS was not reached in the PORT arm and was 81.5 months in the observation arm. The 3-year OS rates were 78.3% in the PORT arm and 82.8% in the observation arm. The 3-year exclusive local recurrence rates significantly differ in the two arms, with 9.5% in the PORT arm and 18.3% in the observation arm.

In both trials, the beneficial effect of PORT in terms of locoregional control did not translate into an increased OS. Even if most patients in Lung ART died of recurrence (155), 18 patients died because of cardiopulmonary diseases and 16 were in the PORT group. As in other studies on lung cancer, there is a risk of additional cardiopulmonary toxicity.[19]

PORT in high-risk patients. Retrospective analyses have identified several possible risk factors for recurrence such as multi-station N2 disease, extracapsular nodal extension, disease in highest removed mediastinal node, lymph node ratio (number of involved nodes/number of explored nodes), and/or inadequate nodal resection.[30-32]

In the Lung ART trial, review of the surgical and pathologic reports was performed according to the definition of complete resection (CR), proposed by the International Association for the Study of Lung Cancer.[32] Thus, by applying this refined definition of CR, going beyond lung tumor margins, to include the status of most distant nodes, nodal capsule, and the performance of an adequate mediastinal lymph node exploration, the percentage of patients having a R0 resection decreased from 99% to 28%.[29] Prognostic factors for DFS include quality of resection, extent of mediastinal involvement, and lymph node ratio.[28] With regard to OS, the extent of nodal involvement is a significant prognostic factor, whereas PORT is not.[28] Secondary analyses of the Lung ART trial may contribute to identifying subgroups where PORT may be effective in terms of tumor control with minimal morbidity.

As there are no randomized data exploring specifically the role of PORT in cN2 resected patients after preoperative chemotherapy, it will be interesting to explore this subgroup of patients (20% of the whole cohort of Lung ART patients). Their relapse rate seems to be high even after CR.[33]

Concerning R1 and R2 resection, two National Cancer Data Base analyses suggest that PORT (alone or in association with chemotherapy) was associated with improved OS.[34,35] Therefore, chemoradiation (sequential or concurrent) is recommended after R1 and R2 resection by the European Society of Medical Oncology, American Society for Radiation Oncology, and ASCO.[36,37]

PORT toxicity. The meta-analyses showed higher cardiopulmonary toxicity and noncancer-related deaths, probably because of less modern techniques, larger volumes, and larger fraction doses in the included studies.[36] Recent evidence highlighting the importance of heart dose in thoracic RT in NSCLC has been published. In particular, a higher dose to some cardiac substructures (such as left anterior descending coronary artery) seems to be correlated with a poorer OS in a recently published reanalysis of the RTOG 0617.[38-40] A systematic review of all dosimetry studies publishing heart doses between 2013 and 2020 showed that mean heart doses were lower with particle therapy and active respiratory motion management, whereas the use of IMRT had no effect in reducing heart doses.[41]

Excess of cardiopulmonary toxicity of the PORT arm was observed in the Lung ART trial, which will be more thoroughly analyzed, with longer-term follow-up. Such analyses of toxicity patterns are awaited as they concern fit patients with cardiovascular comorbidities having received multimodality treatment including surgery. Even if the standard of care for patients with stage IIIA N2 NSCLC may change in the near future, including immunotherapy and surgery, we need long-term follow-up data.

Furthermore, cardiovascular comorbidities may play a synergistic (negative) role not only in radiation but also in other treatments especially when combined.[42]

Perspectives. Evaluation is warranted of more modern radiation techniques such as proton therapy, systematic use of cardiac segmentation, active respiratory management, or any other technique that may select patients who benefit from PORT and reduce cardiopulmonary toxicity. Circulating tumor DNA and other dynamic biomarkers may identify those patients at higher risk of recurrence and potentially those who may benefit from PORT. Ongoing and future trials might clarify which subgroup of patients could benefit from PORT with minimal long-term toxicity.

PERIOPERATIVE SYSTEMIC THERAPY IN NSCLC

Jarushka Naidoo, MBBCh, BAO, MHS, Professor of Medical Oncology at Beaumont RCSI Cancer Centre, Dublin, Ireland, and Adjunct Faculty, Johns Hopkins University

History. Initially published in 2004, the IALT trial randomly assigned patients with resected NSCLC to an adjuvant

cisplatin-based doublet chemotherapy versus observation.[43] In this study, patients received 3-4 cycles of cisplatin in combination with one of either etoposide, vindesine, vinblastine, or vinorelbine. Treatment with the cisplatin doublet was associated with an improved OS of 4.4% at 5 years. After this, the LACE meta-analysis (published in 2008) pooled data from five randomized clinic trials totaling 4,854 patients. This demonstrated a statistically significant improvement of 5.4% in 5-year OS with adjuvant platinum-based chemotherapy.[44] Together, these studies established adjuvant platinum-based chemotherapy as the standard of care for patients with resected stage II-IIIA NSCLC. In the neoadjuvant setting, the NATCH trial investigated three cycles of neoadjuvant versus adjuvant carboplatin/paclitaxel for patients with resectable NSCLC.[45] In the neoadjuvant arm, a greater proportion of patients completed planned therapy (97% *v* 66.2%). Despite this improved treatment exposure, there was no significant difference in DFS or OS between groups. Despite this, a meta-analysis of 15 randomized controlled trials demonstrated that preoperative chemotherapy improves OS and DFS for patients with resectable NSCLC.[18] Taken together, both neoadjuvant chemotherapy and adjuvant chemotherapy are considered options for patients with resectable NSCLC. The critical benefit of adjuvant therapy is the prioritization of the definitive portion of the treatment paradigm (surgery).[46] The benefits of neoadjuvant systemic therapy include early treatment of micrometastatic disease, in vivo assessment of response to systemic therapy, and the increased likelihood of completion of all planned systemic therapies, as demonstrated in the NATCH trial.[45] Furthermore, it provides enhanced tissue for translational research. The recent trials introducing targeted therapies and ICIs into perioperative care represent an exciting advancement. ICIs differ in their mechanism of action compared with chemotherapy, and there is early evidence that neoadjuvant therapy with the primary tumor in place may result in larger and broader pools of T-cell clones directed to tumor antigens and that pathologic tumor response correlates with the robust nature of the T-cell response, which could represent an added benefit of neoadjuvant therapy unique to ICI.[47]

Adjuvant immune checkpoint inhibitors in NSCLC. In the phase III IMpower010 study (n = 1,005), 1 year of adjuvant atezolizumab was compared with best supportive care for patients with resected stage IB-IIIA NSCLC.[48] All patients received adjuvant chemotherapy, and patients whose tumors had known alterations in *EGFR/ALK* were eligible for inclusion. In the intention-to-treat (ITT) population, there was a significant improvement in DFS (HR, 0.81; 95% CI, 0.67 to 0.99). Those whose tumors had a PD-L1 score of >50% appeared to derive the majority of the benefit (HR, 0.43; 95% CI, 0.27 to 0.68). Serious adverse events were uncommon, with 11% of patients suffering from grade 3+ adverse events in the atezolizumab arm. By contrast, in the phase III PEARLS trial (n = 1,177) which investigated the use of adjuvant pembrolizumab, adjuvant chemotherapy was not mandated.[49] DFS was significantly improved in the pembrolizumab ITT population compared with placebo (DFS = 53.6 months *v* 42 months; HR, 0.76; 95% CI, 0.63 to 0.91). Unlike in the IMpower010 study and somewhat counterintuitively, the subgroup that demonstrated the most benefit were those whose tumors had a PD-L1 of 1%-49% (HR, 0.67; 95% CI, 0.48 to 0.92) or harbored EGFR mutations (HR, 0.44; 95% CI, 0.23 to 0.84). However, these subgroups were small. In both studies, OS data are currently immature.

Both studies suggest significant activity of ICIs in the adjuvant setting. The European Medicines Agency (EMA) has licensed adjuvant atezolizumab for patients with a tumoral PD-L1 score of >50% only, whereas the US Food and Drug Administration (FDA) has licensed both atezolizumab and pembrolizumab for patients with a tumoral PD-L1 score of >1% and all-comers, respectively.

NEOADJUVANT IMMUNE CHECKPOINT INHIBITOR MONOTHERAPY

There are 11 phase I and II studies published to date (see Table 1), which have investigated the use of neoadjuvant ICIs without chemotherapy for patients with resectable NSCLC.[50-60] Most of these investigated the use of neoadjuvant ICI without any postoperative therapy. Approaches included the combination of PD-1/PD-L1 with a CTLA-4 inhibitor (NEOSTAR), with stereotactic body radiation (Altorki et al) or with novel agents (NEOCOAST).[50,52,60] These studies demonstrated major pathologic response (MPR) rates ranging from 7% to 50%. The incidence of adverse events was consistent with the known safety profile of ICIs, with the incidence of G3-5 adverse events ranging from 10% to 30%.

NEOADJUVANT CHEMOIMMUNOTHERAPY

There have been five single-arm studies (see Table 2) reported to date investigating neoadjuvant ICI combined with chemotherapy, which include the use of nivolumab, atezolizumab, toripalimab, durvalumab, and sintilimab.[62-66] In these small studies, patients received 2-4 cycles of neoadjuvant platinum doublet-based chemotherapy and an ICI. Most of these studies included patients with stage IB-IIIA NSCLC (see Table 2), and the MPR rate ranges from 22.6% to 83%. Particular highlights include NADIM study enrolled 46 patients with resectable stage IIIA NSCLC, where patients received nivolumab + carboplatin + paclitaxel. In this study of high-risk patients, the MPR rate was an impressive 83% (38 of 46). Moreover, the 1-year DFS was 77% (35 of 46). Although 96% (43 of 46) of patients had a treatment-related adverse event during therapy, only 30% (14 of 46) had a grade 3+ adverse event.

Abbreviations: CR, complete resection; DFS, disease-free survival; EFS, event-free survival; HR, hazard ratio; ITT, intention to treat; IV, intravenous; MPR, major pathologic response; ORR, overall response rate; pCR, pathologic complete response.

One phase II study and one phase III study have been reported to date investigating neoadjuvant nivolumab + chemotherapy versus neoadjuvant chemotherapy alone for three cycles preoperatively. The NADIM-II study enrolled patients with resectable stage IIIA disease, whereas the phase III CheckMate-816 study included patients with stage IB-IIIA resectable NSCLC.[61,67] Both studies excluded patients with activating *EGFR/ALK* mutations. In the NADIM-II study, pathologic complete response (pCR) rates were significantly higher compared with chemotherapy alone (36.2% *v* 6.8%, *P* = .0071) and similarly for both MPR (52% *v* 14%) and objective response rates (74% *v* 48%). In addition, there was a significant improvement in OS at 24 months in the experimental arm (85.4% *v* 64.8%; HR, 0.37; 95% CI, 0.14 to 0.93). In the CheckMate-816 study, pCR with the addition of nivolumab to chemotherapy alone were 24% versus 2% and this effect was seen across prespecified subgroups.[61] Moreover, MPR was significantly improved with the addition of nivolumab (36.6% *v* 2.2%) compared with chemotherapy. In preliminary results, there was a trend toward an OS improvement with the addition of ICI to chemotherapy (HR, 0.57; 95% CI, 0.38 to 0.87). In both studies, there was a higher incidence of grade 3+ adverse events in the experimental arms (24%-33% *v* 10%-11%). There was no unexpected surgical morbidity or mortality observed in these studies.

ADJUVANT AND NEOADJUVANT THERAPIES FOR PATIENTS WITH EGFR/ALK ALTERATIONS

For patients whose tumors harbor an activating *EGFR* mutation, the success of first- and second-generation tyrosine kinase inhibitors (TKIs) in the metastatic setting resulted in a number of trials investigating their role in the adjuvant setting with disappointing results.[68,69] In the ADAURA study, adjuvant use of the third-generation TKI, osimertinib, was investigated for patients with resected stage IB-IIIA *EGFR*-mutant NSCLC. In this study, adjuvant chemotherapy was recommended but not mandated and patients were randomly assigned to 3 years of osimertinib versus placebo.[70] A total of 682 patients were randomly assigned in this study, 410 of whom received adjuvant chemotherapy. This study demonstrates a DFS benefit in favor of osimertinib (HR, 0.20; 95% CI, 0.14 to 0.3). In the osimertinib group, 90% of patients were alive and disease-free at 24 months compared with 44% in the placebo group. OS data remain immature. This regimen has been approved by both the FDA and EMA.

First-generation *EGFR* TKIs have also been investigated in five phase II studies in the neoadjuvant setting in a total of 124 patients.[71-75] The primary end point in each of these studies was objective response rate, which ranged from 42% to 58.3%. These encouraging data have resulted in the ongoing phase III NEOADAURA study, which is

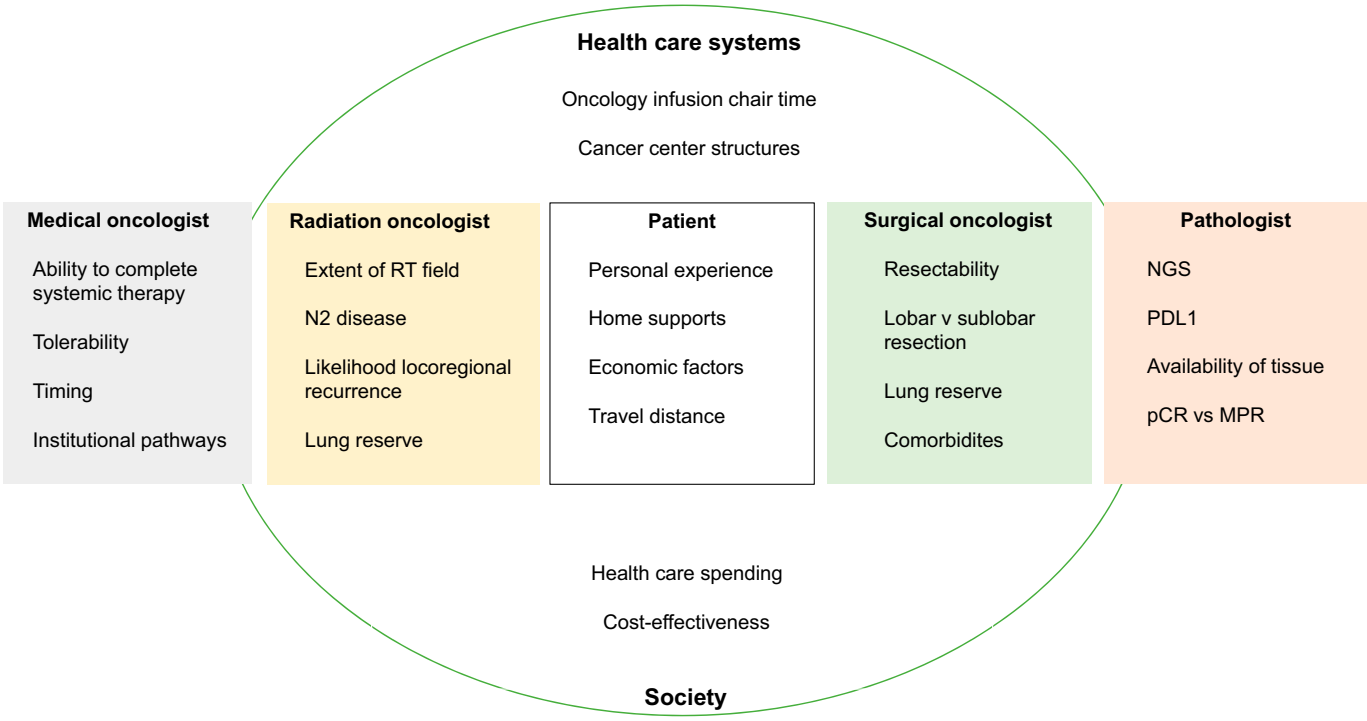

FIG 2. Factors in selection of perioperative approaches in non–small-cell lung cancer. MPR, major pathologic response; NGS, next-generation sequencing; pCR, pathologic complete response; RT, radiotherapy.

investigating neoadjuvant osimertinib for patients with resectable NSCLC.[76] For patients with *ALK*-rearranged NSCLC, case studies and small trials have demonstrated activity with neoadjuvant crizotinib and alectinib.[77,78] The phase III ALINA study is currently underway and will investigate the role of adjuvant alectinib in patients with resected *ALK*-rearranged NSCLC.[79] Finally, the ongoing phase III ALCHEMIST study offers biomarker analysis and targeted therapy for patients with stage IB-IIIA resected NSCLC (erlotinib, crizotinib, nivolumab, pembrolizumab + chemotherapy) and may provide further data in this field.

OPTIMAL SYSTEMIC THERAPY FOR RESECTABLE NSCLC: WHICH APPROACH IS BEST?

FDA-/EMA-approved regimens for patients with resectable NSCLC now include adjuvant atezolizumab/pembrolizumab, neoadjuvant nivolumab with chemotherapy, and adjuvant osimertinib. The decision as to which approach to pursue is influenced by patient preference, performance status, disease staging, presence of tumoral *EGFR/ALK* alterations, PD-L1 status, and institutional pathways (see Fig 2).

DISCUSSION

In this article, we have reviewed advances in the multidisciplinary management of patients with resectable NSCLC.

The CALGB/Alliance Trial and the JCOG0802/WJOG4607 study have both demonstrated that sublobar resection is a standard of care for select patients with stage IA1/IA2 NSCLC. It is hoped that this de-escalation of therapy may improve our patients' quality of life by preserving pulmonary parenchyma associated with the more extensive lobar resection. In clinical practice, the development of surgical pathways equivalent to both these studies may be challenging (eg, intraoperative frozen sections of nodal stations). Despite this, it is likely that sublobar resection will become a new standard of care for a select group of patients with NSCLC. Further developments in the surgical management of NSCLC include the increasing role of minimally invasive surgery, which now plays a key role in current surgical practice. De-escalation of surgical resection may be a component of future clinical trials for patients with NSCLC.

Given the high rates of relapse after resection of NSCLC, the benefits of adjuvant PORT have been investigated in several contemporary clinical trials (most recently, Lung ART and PORT-C). Evaluating the benefits of historical prospective studies has been challenging given the emergence of modern radiotherapy techniques associated with improved treatment accuracy and lower toxicity. The risk of cardiopulmonary toxicity post-PORT remains a clinical challenge and may negate some of the survival benefits with regard to disease control and mortality. Despite this, PORT is recommended for a subset of patients with high-risk resected NSCLC (R1/R2 resection) and it may play a role in patients with other high-risk features. Modern radiotherapy techniques such as proton therapy or systematic use of cardiac segmentation may allow the delivery of doses necessary for tumor cell death while preserving surrounding normal tissues. Future prospective work will likely investigate these modern techniques in conjunction with the recent advances seen in surgical and medical oncology.

With three new FDA regimens approved in the perioperative setting, ICIs are undoubtedly a new standard of care for patients with resectable stage IB-IIIA NSCLC. The conflicting subgroup analyses of PEARLS and IMpower010 raise questions regarding the role of PD-L1 status as a predictive biomarker in this setting, differenced in the study populations, and differing efficacy of PD-1 and PD-L1 inhibitors. Given the shorter treatment duration and convincing EFS benefit in CheckMate-816, this neoadjuvant regimen may be favored. Looking to the future, we eagerly await OS data for the studies already reported. There are ongoing randomized phase III studies investigating nivolumab (ANVIL) and durvalumab (AEGEAN) in similar settings to IMpower010 and PEARLS.[80] Beyond this, novel approaches may involve de-escalation of therapy for those who have a pCR at the time of surgery and the use of ctDNA for treatment selection, monitoring, and even duration.

We are fortunate to work in an era with clinical advances in the management of NSCLC, resulting in tangible improvements in outcomes for patients. Critical questions remain with regard to the most appropriate conditions for sublobar resection, the need for intraoperative staging, and the optimal timing and choice of systemic agents to achieve the best outcomes for our patients. To date, the evidence supports the utilization of these advances, but defining a therapeutic strategy for each patient is increasingly complex (see Fig 1). Given this increasing complexity, decisions regarding perioperative approaches must be made in a collaborative multidisciplinary manner.

Family Matters: Germline Testing in Thoracic Cancers

Feighanne Hathaway, MS, LCGC[1]; Renato Martins, MD, MPH[2]; Steven Sorscher, MD[3]; Aleksandra Bzura, PhD, MSc[4]; Frank Dudbridge, PhD[4]; and Dean A. Fennell, PhD, FRCP, FRSB[4,5]

Overview

Most thoracic cancers arise via a series of stepwise somatic alterations driven by a well-defined carcinogen (ie, tobacco or asbestos for lung cancer and mesothelioma, respectively). A small proportion can emerge on a background of pathogenic germline variants (PGVs), which have the property of heritability. In general, PGVs may be initially suspected on the basis of the presence of specific clinical features. Such gene × environment interactions significantly increase the risk of developing lung cancer (1.5- to 3.2-fold). PGVs have been discovered involving the actionable driver oncogene, epidermal growth factor receptor (EGFR), with an *EGFR* T790M PGV rate of 0.3%-0.9% in the nonsquamous non–small-cell lung cancer subtype. Its appearance during routine somatic DNA sequencing in those patients who have not had a previous tyrosine kinase inhibitor should raise suspicion. In patients with sporadic mesothelioma, *BAP1* is the most frequently mutated tumor driver, with a PGV rate between 2.8% and 8%, associated with a favorable prognosis. *BAP1* PGVs accelerate mesothelioma tumorigenesis after asbestos exposure in preclinical models and may be partly predicted by clinical criteria. At present, routine germline genetic testing for thoracic cancers is not a standard practice. Expert genetic counseling is, therefore, required for patients who carry a PGV. Ongoing studies aim to better understand the natural history of patients harboring PGVs to underpin future cancer prevention, precise counseling, and cancer management with the goal of improving the quality and length of life.

BASICS OF GERMLINE TESTING AND APPROACHES TO GENETIC COUNSELING IN THORACIC CANCER

The vast world of clinical cancer genetics has changed rapidly over the past several years, which one could argue, began with the 2013 Supreme Court of the United States ruling that companies may not patent genes.[1] That ruling and the use of next-generation sequencing allow many laboratories to offer genetic testing at a reduced cost and to sequence multiple genes at a reduced cost. As a result, there has been an increase in the use of genetic tumor profiling to drive treatment options and therapy.[2] With this expansion, the approaches to germline genetic testing and their uses have changed over a brief period. These changes have occurred throughout many tumor types; however, germline genetic testing has yet to be integrated as the standard of care in the thoracic setting.[3,4]

What Is Genetic Counseling?

Genetic counseling is not a therapy nor counseling in the traditional sense of the word. According to the National Society of Genetic Counselors, "genetic counseling is the process of helping people understand and adapt to the medical, psychological and familial implications of genetic contributions to disease."[5] In the cancer setting, genetic counselors help patients understand the genetic make-up of their cancer, how this genetic make-up affects treatment, future cancer risks, and risk to other family members. Therefore, it is imperative that cancer genetic counselors have a thorough understanding of not only genetics but also cancer. It is often the first time in a patient's journey that they are allotted the time to fully understand their disease.

Suspecting an Inherited Mutation in a Thoracic Cancer

Although all cancers have a genetic origin, not all cancers are hereditary. Around 5%-10% of all cancers are hereditary in nature.[6] Some key features to consider when identifying a potentially inherited cancer include an early age of onset, bilateral/multifocal disease, more than one cancer diagnosis in an individual, aggressive or rare tumor, family history, and ethnicity.[7] In addition, the tumor's genetic profile highlights a potential germline or inherited alteration. For this reason, ASCO guidelines suggest that oncologists inform patients that an incidental germline variant could be identified before ordering a genomic tumor profile.[8] For example, if a genetic tumor profile reveals a mutation in *TP53* with a variant allele fraction ≥40%, this may suggest a germline mutation in *TP53* rather than a somatic alteration. However, not all germline mutations are present in a tumor, so there may still be a need for germline genetic testing even after the genetic profiling of a tumor.[8-10]

PRACTICAL APPLICATIONS

- The National Comprehensive Cancer Network lacks specific guidelines for managing lung cancer patients with genetic mutations and little mention of genetic testing (Table 1). Standardizing genetic testing can improve patient care, reduce disparities, and ensure all patients receive the same level of care. Genetic testing in the thoracic setting can identify mutations to guide treatment options, identify at-risk family members, and facilitate data sharing for a more comprehensive understanding of inherited cancer syndromes. Collaboration can lead to identifying new targets for therapy and screening modalities, ultimately improving patient care, and promoting access and equity in health care.
- The prevalence of genetic variants that increase the risk of lung cancer is high. Germline profiling of patients with lung cancer may affect their management, including screening recommendations and clinical trial opportunities. As testing becomes cheaper and more available, it is likely that germline profiling will improve our understanding of the interactions between pathogenic germline variants and lung cancer development and between genetic polymorphisms and treatment outcomes.
- BAP1 mutations are associated with an increased risk of developing mesothelioma and other types of cancers, such as uveal melanoma and renal cell carcinoma. Testing for these mutations can help identify individuals and family members who may be at increased risk of developing these cancers and allow for earlier surveillance and intervention. Genetic counseling can help these individuals understand their risk and make informed decisions about genetic testing and cancer screening. Overall, BAP1 germline testing in patients with mesothelioma can provide important information for cancer risk assessment, treatment decision making, and genetic counseling.

Genetic Counseling in the Thoracic Setting

Through the emergence of genetic tumor profiling, we are discovering new associations with not only known DNA repair genes and tumor suppressor genes but also within genes that were not typically associated with cancer (eg, *NOTCH1* and *RECQL1*).[2,4,11] This crossover between subspecialties within genetic counseling is changing the scope of practice and increasing the need for experts who understand this crossover.

As routine germline genetic testing in the thoracic setting is not the standard in the United States, counseling of patients is different compared with solid tumors such as breast or colon cancer. Unlike other tumor settings, patients with thoracic cancers have somatic mutation testing before germline testing. Genetic counselors need to have a thorough understanding of the somatic alterations in thoracic tumors and their interpretation. Somatic alterations may reveal germline mutations that are not obvious by tumor type or family history alone, which are known as an anticipated incidental finding.[12] These results are often frustrating and confusing to a patient who is already suffering from a cancer diagnosis. This is especially true in the thoracic setting where little has been studied regarding known germline variations.

Once a risk of thoracic cancer is identified in the family, there is little known regarding the standard of care for screening of thoracic cancers in the United States. This lack of standard of care makes it difficult to offer patients guidance in screening and relies heavily on small case studies as guides to screening.[13] This can often leave the patient with more anxiety and stress. In addition, insurance coverage for screening in these instances is often denied, which can also be an additional financial burden placed on the family.[14-16]

HEREDITARY LUNG CANCER

Lung cancer is the most common cause of cancer mortality worldwide. In fact, the combined annual mortality from colorectal, pancreatic, and breast cancers is less than the annual mortality from lung cancers alone in the United States.

Most lung cancers are thought to be related to environmental risk factors, such as cigarette smoking or radon exposure. Genes associated with nicotine addiction and polymorphisms in genes, which inadequately metabolize cigarette-containing carcinogens when expressed, contribute to lung cancer development. These genes, which are inherited, would not be considered pathogenic germline variants (PGVs). However, their relation to lung cancer development indicates that many, if not most, lung cancers have a genetic link contributing to their development.

PGVs are inherited genes that sometimes predispose individuals to cancer. In this section, we discuss the inherited genes that place individuals at risk of developing lung cancer that would not be referred to as PGVs. We also discuss PGVs that predispose individuals to developing lung cancer.

Genetic Pathogenic Variants and Lung Cancer Risk Among Smokers

Smokers with a family history of lung cancer in a first-degree relative have a much higher chance of developing lung

cancer than those without. Investigators from the International Lung Cancer Consortium evaluated almost 50,000 lung cancer cases and controls and their family histories.[17] Overall, individuals who have a first-degree relative with lung cancer had a 1.5-fold increase in risk. Among smokers who had a first-degree relative with lung cancer, the risk was 3.2-fold higher. These data suggest that germline genetic characteristics increase the susceptibility of developing lung cancer when exposed to toxins in tobacco. The association between chronic obstructive pulmonary disease (COPD) and the development of lung cancer,[18] adjusted for tobacco exposure, also suggests that lungs damaged from tobacco exposure are more susceptible to the development of lung cancer. A parental history of COPD is associated with an increased risk of developing COPD.[19]

These associations may, in part, be explained by the activity of nicotine acetylcholine receptors, which are a family of ligand-gated cation channels activated endogenously by acetylcholine and exogenously by chemicals, such as nicotine. A single-nucleotide polymorphism (SNP) in one of its subunits is associated with a significant increase in nicotine dependence and the development of lung cancer.[20] It is hard to distinguish the increase in tobacco consumption due to this SNP versus the potentially direct, negative biological effect of lung cancer development resulting from this polymorphism because the receptors in individuals harboring this polymorphism have been associated with both cell proliferation and apoptosis.

Hereditary Lung Cancer With EGFR Pathogenic Variants

Acquired somatic point mutation T790M of the epidermal growth factor receptor (EGFR) tyrosine kinase (TK) domain confers resistance to first- and second-generation oral EGFR inhibitors.[21] Although some activating mutations of the TK domain are incompatible with normal embryonic development, the T790M is a proven *EGFR* PGV.[22] Tumor interrogation revealing an *EGFR* T790M in the lung cancer of a patient who was not previously exposed to tyrosine kinase inhibitor therapy suggests that this is an *EGFR* T790M PGV and should prompt referral for genetic counseling according to the current National Comprehensive Cancer Network (NCCN) guidelines.

Similarly, the NCCN guidelines (Table 1) suggest that if a mutation is identified in a lung cancer that is not a typical lung cancer somatic mutation, and particularly if the mutational allelic frequency of that gene suggests the identified alteration represents an incidental PGV, these patients with lung cancer should be considered for genetic counseling.

Interestingly, most of the adenocarcinomas associated with this PGV do have a second somatic activating mutation of the *EGFR* TK domain.[23] Lung cancers associated with the *EGFR* T790 PGV represent 0.3%-0.9% of all cases of nonsquamous NSCLC.[4] On the basis of a review of the literature and an analysis of a large family, Gazdar et al concluded that the lifetime risk likelihood of developing NSCLC in individuals harboring an *EGFR* T790M PGV is very high. The authors reported 19 lung cancer cases developing among 29 carriers. This extremely elevated risk justifies a discussion about family genotyping and screening for lung cancer for those carriers of the *EGFR* T790M gene. The use of magnetic resonance imaging, starting as early as age 20 years was suggested by Gazdar et al,[8] although no established penetrance statistics or screening recommendations are currently available.

TABLE 1. NCCN Guidelines for Hereditary Cancer Testing

NCCN Guidelines Version 3.2023 for Hereditary Cancer Testing
General Testing Criteria
Testing is clinically indicated in the following scenarios:
Individuals with any blood relative with a known P/LP variant in a cancer susceptibility gene
Individuals meeting the criteria below but who tested negative with previous limited testing (eg, single gene and/or absent deletion duplication analysis) and are interested in pursuing multigene testing
A P/LP variant identified on tumor genomic testing that has clinical implications if also identified in the germline
To aid in system therapy and surgical decision making
Individuals who meet LFS testing criteria or Cowden syndrome/PHTS testing criteria or Lynch syndrome
Testing *may* be considered in the following scenario (with appropriate pretest education and access to post-test management):
An individual of Ashkenazi Jewish ancestry without additional risk factors
Personal history of serous endometrial cancer

Abbreviations: LFS, Li-Fraumeni syndrome; NCCN, National Comprehensive Cancer Network; P/LP, pathogenic/likely pathogenic; PHTS, PTEN hamartoma tumor syndrome.

Lung adenocarcinomas that develop in never smokers and have an activating *EGFR* mutation are more common among female patients and those of Asian ethnicity.[24] This suggests that polymorphisms that predispose to *EGFR* somatic mutations might be found more commonly in these groups. Currently, these polymorphisms or the mechanism of tumorigenesis in these patients is not well-understood but warrants further investigation.

Another poorly understood association is that between Li-Fraumeni syndrome (LFS) and *EGFR*-mutated lung cancer. LFS is a cancer susceptibility syndrome associated with a *TP53* PGV. Individuals with LFS are at a particularly elevated risk of developing sarcomas, leukemia, brain tumors, adrenal cortical carcinoma, breast cancer, choroid plexus tumors, and lung adenocarcinomas. European investigators[25] identified 22 patients with lung cancer and Li-Fraumeni

syndrome. Of 25 patients, 17 (68%) had an activating *EGFR* mutation, of which 15 had the most common exon 19 deletion or L858R. Of note, one additional patient had a *ROS-1* fusion. Only two of these patients were former smokers, and 76% had stage IV disease on presentation.

Breast cancers associated with Li-Fraumeni syndrome have been correlated with higher rates of human epidermal growth factor receptor 2 (HER2) overexpression.[26] This association suggests that HER family-driven carcinogenesis is associated with the increased chromosomal instability in the context of a *TP53* PGV. A novel germline *HER2* G660D PGV has been reported in a Japanese family with familial lung adenocarcinomas.[27]

Presence of Pathogenic Variants in the General Lung Cancer Population

Universal germline testing of all patients with lung cancer would be justified if identified PGVs were to have an implication for the screening or management or implications for their families. The other reason to perform such analysis or pharmacogenomic profiling for polymorphisms is to understand the factors influencing the natural history of lung cancer. For example, patients who have advanced adenocarcinoma of the lung may have prolonged disease control on maintenance pemetrexed. It is unknown whether these patients have a somatic mutation profile that predicts the observed prolonged response or that remarkable benefit is that related to a polymorphism or PGV that affects the efficacy of the pemetrexed.

Although a discussion of the pros and cons of broad germline testing in patients with cancer is beyond the scope of this review, readers are directed, for example, to the recent excellent discussion using GI malignancies as the model proposed by Hampel and Yurgelun.[28] Germline testing is considered the standard of care for all or many patients with ovarian, pancreatic, colorectal, breast, and prostate cancers. Investigators from Memorial Sloan Kettering evaluated the germlines of 12,000 patients diagnosed with advanced cancer.[29] In their study, 9% of the patients had a likely pathogenic/pathogenic (LP/P) variant. The most common PGVs identified were in *BRCA1/2*, *CHEK2*, *ATM*, mismatch repair genes and *PALB2*. Lung cancer was under-represented in their germline analysis, and results of this group were not reported. Investigators from China analyzed 1,026 patients with lung cancer and performed a germline analysis using a 58-gene next-generation sequencing panel.[30] When combining pathogenic (P) and likely pathogenic (LP) variants, they found a PGV prevalence of 4.7%. The most common PGVs were in *BRCA2*, *CHEK2*, and *ATM*.[31-33]

In another study, 7,788 patients with lung cancer were evaluated for PGVs.[34] The diagnosis prompting germline testing was lung cancer, and the gene panel chosen was based on the clinician's choice. In this study 1,161 patients with a LP/P variant, with a prevalence of 14.9%. The most common were in *BRCA2* (2.8%), *CHEK2* (2.1%), *ATM* (1.9%), *TP53* (1.3%), *BRCA1* (1.25), and *EGFR* (1%). The high-prevalence results appeared to suggest that the germline tests were ordered because the clinician was suspicious of a PGV, not on the basis of the lung cancer diagnosis but rather the personal or family histories of these patients with lung cancer. However, patients without and with personal or family histories of non–lung cancers had similar rates of these variants (14.5% *v* 16%, respectively).

Although it is likely that the true percentage of PGVs in the lung cancer population is lower than the 14.9% observed in this study raised the question of whether PGVs other than *TP53* and *EGFR T790*, such as *BRCA2* and *CHEK 2*, should be considered—or at least further studied—as lung cancer predisposing.

Another interpretation of this findings is that patients diagnosed with lung cancer are inadequately considered for germline testing before their diagnosis. In other words, if the patients in this study were tested because of their personal or family histories of non–lung cancer, provided these patients were evaluated in other clinics before their diagnosis of lung cancer, providers in those clinics either were unaware of the personal or family histories that should prompt referral for genetic counseling or did not adequately assess whether these patients had personal or family histories suggesting a high pretest probability of carrying a PGV. A family history must be part of a comprehensive lung cancer evaluation, and when such history suggests the possibility a germline variant that may affect cancer development, the prevalence of 15% justifies germline analysis testing.

Small-cell lung cancer represents around 10% of the lung cancer population. Inherited susceptibility has been identified by germline whole-exome sequencing of 87 patients, 43.7% of whom had 42 PGVs involving 35 cancer-predisposing genes. The results were independently cross-validated, including PGVs involving *RAD51D*, *CHEK1*, *BRCA2*, and *MUTYH*.[35]

GERMLINE ALTERATIONS AND INHERITED PREDISPOSITION IN MESOTHELIOMA

Exposure to asbestos has long been the principal environmental carcinogen causally associated with the etiology of mesothelioma. However, a substantial body of data has emerged over the last five decades that implicates germline predisposition as a component of risk associated with this cancer.

A case-control study in the 1970s hinted at familial clustering in a cohort of 52 female patients, in whom it was observed that the parental risk of cancer was significantly greater in cases compared with controls, raising the

possibility of germline predisposition.[36] This finding was also observed independently[37,38] reinforcing this possibility.

Robust confirmation of heritable transmission followed a genetic epidemiological analysis involving six generations and 526 individuals in the Cappadocia region of Turkey, in which the rate of mesothelioma in the villages of Jarain and Tuzkoy was as high as 50% and unrelated to the abundance of erionite asbestos in both affected and unaffected neighboring villages.[39] Genetic predisposition modulates sensitivity to asbestos. This was inferred in the Cappadocia study on the basis of the finding that family members born and raised outside of these villages did not develop mesothelioma.

Genome-Wide Association Studies

It is probable that mesothelioma has a heritable polygenic component, in common with other multifactorial conditions. However, progress in identifying polygenic risk has been hindered by the requirement for very large sample sizes. Genome-wide association studies have been conducted in case-control samples in Italy,[40] with 407 cases and 389 asbestos-exposed controls, and in Australia,[41] with 428 cases and 1,269 controls. Neither study identified SNPs with associations stronger than chance expectation. However, the study conducted in Italy reported suggestive signals in regions previously associated with somatic mutations in mesothelioma, including *SLC7A14*, *THRB*, *CEBP350*, *ADAMTS2*, *ETV1*, *PVT1*, and *MMP14*. Neither study succeeded in directly replicating the results of the other, although the study conducted in Australia reported suggestive associations in *SDK1* with some evidence of replication in the study conducted in Italy.

The recent emergence of large national biobanks has increased the number of genotyped cases available, albeit with lower quality data on asbestos exposure. Unpublished genome-wide association study (GWAS) results are available on the Internet for the UK Biobank,[42] with 165 cases and 361,029 controls (http://www.nealelab.is/uk-biobank), and FinnGen,[43] with 298 cases and 259,583 controls (https://www.finngen.fi). Again, these studies have not identified associations stronger than chance expectation and have not replicated the strongest signals from other GWAS.

GWAS data allow the estimation of heritability from ostensibly unrelated individuals, providing evidence for the presence of polygenic associations. In the UK Biobank, this was estimated at 0.7734 with SE 0.358[44]; however, this estimate is likely to be numerically unstable given the limited sample size. In view of the dominating environmental risk from asbestos exposure, any polygenic heritability is likely much smaller but is not ruled out by the UK Biobank estimate.

Currently then, sample sizes remain insufficient for reliable identification of common germline variants increasing mesothelioma risk. However, meta-analysis of extant results with integration of data from multiple biobanks[45] may soon allow greater progress in this area.

BAP1 and Predisposition to Mesothelioma

BRCA1-associated protein (BAP1[46]) is one of the most frequently mutated tumor suppressors in patients with mesothelioma. It functions as a deubiquitinating enzyme and subunit of the polycomb transcriptional repressor complex. BAP1 PGVs (^Fig 1) are associated with a loss of BAP1 nuclear localization, which is critical for DNA repair, chromatin assembly, or transcription.[47] Because the carboxy terminus of the BAP1 protein contains the nuclear localization signal, all truncating mutations are pathogenic and the truncated BAP1 protein is found in the cytoplasm.

A link between BAP1 and germline susceptibility was identified in connection with metastatic uveal melanoma, renal cancer, cutaneous melanoma, and basal cell carcinomas.[48,49] Approximately one third of carriers develop two to seven malignancies in their lifetime, with malignant mesotheliomas being frequent.[49-56]

BAP1 germline mutations were originally found in two families with a high incidence of mesothelioma.[57] Genealogic studies traced a common ancestor from the 1700s associated with a large BAP1 cancer syndrome kindred over nine generations.[58] Biallelic inactivation (ie, a second hit) can arise after both germline and subsequent somatic alterations. Recently, however, germline whole BAP1 gene deletion has been found in a family.[59] Preclinical studies have shown that the onset of mesothelioma after asbestos exposure is accelerated in germline BAP1(±) mice, consistent with a gene × environment interaction.[60,61]

In patients, germline BAP1 mutation affects a fraction of patients with mesothelioma, originally reported at 8% (2 of 26) in the first reported series,[57] with some studies reporting low or absent germline BAP1 alterations.[62] *The Clinical and Histopathologic Characteristics of BAP1 Mutations study* (ClinicalTrials.gov identifier: NCT01773655) recently reported the prevalence of pathogenic BAP1 germline mutations to be 5 of 180, which were found exclusively in those patients predicted by the following clinical screening criteria: (1) a personal or family history of choroidal nevus, uveal melanoma, melanoma, mesothelioma, renal cancer, or cholangiocarcinoma; (2) a history of cancer in >two first-degree relatives; (3) no known history of asbestos exposure; and (4) age younger than 50 years at diagnosis.[63] These results confirm the low rate of pathogenic BAP1 germline mutations in patients with mesothelioma.

The prognosis for patients diagnosed with germline BAP1 mutation is particularly good. In a series of 79 patents, this

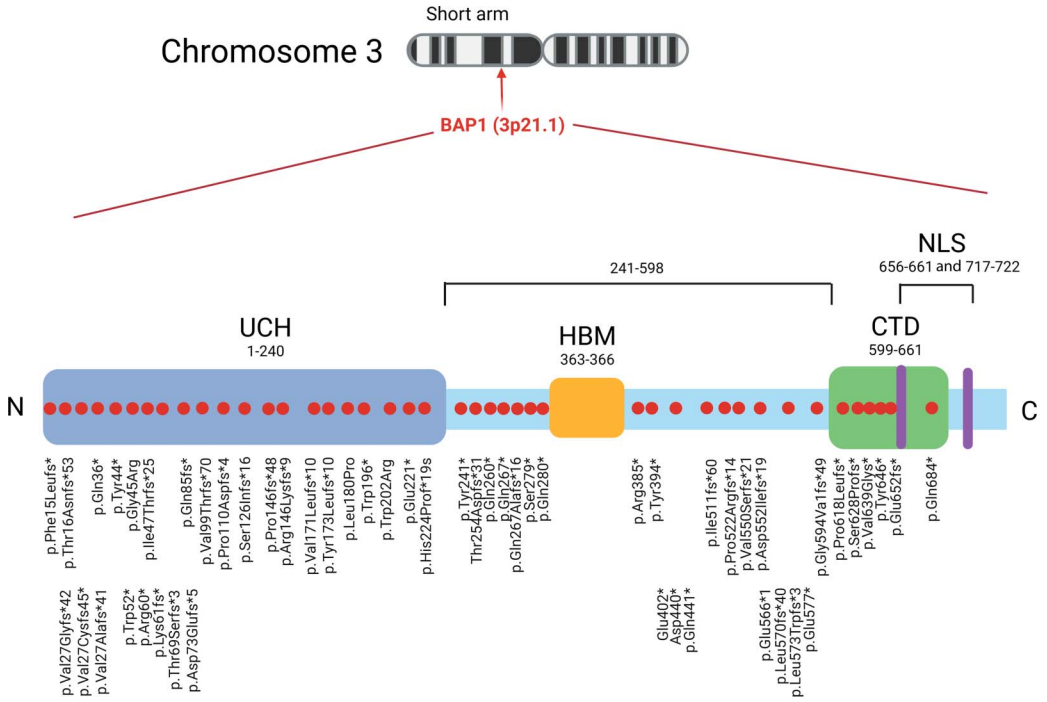

FIG 1. A schematic summarizing reported *BAP1* PGVs in patients with mesothelioma. Mutation hotspots are evenly distributed across multiple protein domains (red dots). CTD, C-terminal domain; HBM, host cell factor 1–binding domain; NLS, nuclear localization signals; PGV, pathogenic germline variant; UCH, ubiquitin carboxyl-terminal hydrolase domain.

was 9 years versus 8 months across all stages in the SEER cohort.[64] Another study showed a 7-fold increase in survival for germline *BAP1* mutations in patients with mesothelioma.[65]

The penetrance of the heterozygous nonfunctional *BAP1* allele in the clinically confirmed families has reached 100%; approximately one third of carriers develop two to seven malignancies in their lifetime, with malignant mesotheliomas being frequent.[49-56] Interestingly, 9.7% to 12% of all patients with mesothelioma have shown to acquire pathogenic germline mutations, which most affects *BAP1*.[64,66,67] These alterations are more common in young individuals and those who have a family history of the disease.

Pleural and peritoneal mesotheliomas may develop simultaneously or years apart in *BAP1* mutation carriers.[47,68] Affected people also develop benign melanocytic intradermal tumors and malignancy around 20 years earlier than the same malignancies occurring sporadically.[58,64,65,69]

Mesotheliomas are among the less aggressive cancers that develop in germline *BAP1* mutation carriers.[47] The median survival for mesothelioma in these patients is 5-7 years after diagnosis, with 26% of patients surviving 10 or more years.[64,69] Depending on the histology, the median survival for sporadic mesothelioma ranges from 6 to 24 months.[70]

Genetic Counseling and Mesothelioma

One of the greatest differences when counseling patients in the thoracic setting is when a patient has a diagnosis of mesothelioma. As previously mentioned, mesothelioma can be associated with mutations in *BAP1*, which can be inherited or somatic. Many patients with mesothelioma are involved with litigation when it comes to their personal diagnosis of mesothelioma due to exposure to asbestos. Many of these patients are rightfully concerned that if a germline mutation is identified, this can be used against them. That is, the defense could argue that the asbestos exposure had little to no effect on cancer diagnosis and that the cause of the cancer was due to an underlying predisposition to mesothelioma. Although it is a standard practice to discuss the Genetic Information Non-Discrimination Act (GINA) with all patients, this litigation area of concern is specific to patients with mesothelioma.[63] It is imperative that genetic counselors discuss this potential with patients so that they can make the best decision for themselves regarding genetic testing. Viable alternative options may (1) include a decline in germline genetic testing or (2) choose to undergo genetic testing under a research study to keep this information separate from their medical record.

Prospective studies have been designed to help underpin cancer prevention, precise counseling, and cancer

management in patients with germline BAP1 mutation. These include a study enrolling 500 patients with a family history suggestive of hereditary *BAP1* is being investigated, as well as individuals with variants that are known to be or are potentially pathogenic or of uncertain significance (ClinicalTrials.gov identifier: NCT04792463 due for completion in 2026). The goal is to develop novel screening, prevention, and treatment strategies by investigating the prevalence of germline *BAP1* in mesothelioma as well as melanoma, renal cell carcinoma, cholangiocarcinoma, hepatocellular carcinoma, meningioma, and basal cell carcinoma (BAP1 syndrome cancers).

Long-term Follow-up of Mesothelioma Patients and Their Family Members with Germline Mutations in BAP1 and Other Genes (ClinicalTrials.gov identifier: NCT03830229 due for completion in 2027) is an observational study designed to characterize the clinical history of malignant mesothelioma in 1,000 patients and their first-degree relatives who have a *BAP1* or *TP53* mutation. The study will use periodic MRI scans and breast, skin, and ocular examination.

A study designed to improve how people with known or suspected BAP1 mutations are monitored over time (ClinicalTrials.gov identifier: NCT04431024 due for completion in 2038) will recruit 800 participants to undergo dual-energy computed tomographic imaging, longitudinal noninvasive (liquid) biopsy, and minimally invasive surgical surveillance. Participants are eligible if they are older than 30 years, with a history of any malignancy, are with a germline *BAP1* mutation involving *BAP1*, or are a first- or second-degree relative of someone with a known germline *BAP1* mutation. Tumor tissue, blood, saliva, or buccal swab specimens will be sampled for genetic analyses to explore the biological mechanisms associated with the favorable prognosis of germline *BAP1* mutation.

SUMMARY

Routine germline genetic testing for thoracic cancers is not currently the standard practice; however, ongoing studies aim to better understand the natural history of patients with PGVs to improve their clinical management.

overview

Antibody Drug Conjugates (ADCs) are a novel class of therapeutic that structurally comprise an antibody directed at a tumor epitope connected via a linker to a cytotoxic payload that have shown significant antitumor activity across a range of malignancies including lung cancer. In this article we review the pharmacology of ADCs, describe results of trials with ADCs directed at targets in lung cancer including Trophoblast cell-surface antigen 2(TROP2), HER3, MET, Carcinoembryonic antigen-related cell adhesion molecular 5(CECAM-5) and HER2. Trastuzumab Deruxtecan (also known as DS-8201a or T-DXd) an ADC directed at HER2 recently became the first ADC to receive FDA approval in lung cancer, on the basis of its activity in tumors with HER2 mutations, demonstrated in the Destiny-Lung01 and Lung02 trials.

INTRODUCTION

The historical roots of antibody-drug conjugates (ADCs) trace back to the early 20th century when Paul Ehrlich conceived of a more targeted delivery of anticancer therapy termed the magic bullet.[1] Indeed, a century of advancement in the fields of biochemistry, pharmacology, and immunology has converged and led to the development of these novel therapeutic agents that demonstrate clinically meaningful activity with immense potential to alter the treatment paradigm in non–small-cell lung cancer (NSCLC). The rationale of ADCs is simple: selectively target cancer cells and deliver concentrated cytotoxic payloads through an antibody-mediated process, effectively sparing normal tissue and inflicting increased damage to tumors. In addition to the direct cytotoxic effects, additional innate and adaptive immune mechanisms may further potentiate anticancer effects both regionally and systemically.[2] As such, modern ADCs have been developed to maintain pharmacodynamic stability in the compartment of systemic delivery (ie, the blood), preferentially bind to a target antigen expressed on cancer cells leading to accumulation within the tumor compartment, become internalized by the target cell, and release cytotoxic levels of the chemotherapy payload. This precise delivery mechanism may ultimately lead to an increased therapeutic index of the corresponding payload compound, in theory limiting what may otherwise be toxic effects at equivalent systemic doses. These agents have had increasing impact in both solid tumor and hematologic malignancies, with recent advances in the treatment of oncogene-driven and non–oncogene-driven NSCLC.[3,4] Here, we provide an overview of the pharmacology of design of ADCs and review advances with ADCs directed at targets in lung cancer including trophoblast cell-surface antigen 2, HER3, MET, carcinoembryonic antigen-related cell adhesion molecular 5 and discuss developments in targeting HER2 leading to the approval of trastuzumab deruxtecan (T-DXd) for *HER2* mutation–positive NSCLC.

THE ABCs OF ADCs

Design of ADCs

Three key elements of ADC design include the antibody, linker, and payload. Each of these components have undergone significant refinement in recent decades, culminating in more clinical activity and tolerability, but also leading to important variability and distinctions between ADCs.

Antibody and antigen target. Selecting an appropriate target and consequently designing a corresponding antibody against this target are essential aspects to successful ADC development. An ideal protein target is one that is highly expressed on the cell surface of cancer cells, with limited expression levels on nonmalignant tissues.[5] Current targets of ADCs, including HER2,[6] TROP2,[7] and HER3,[8] exhibit higher expression levels on tumor cell surfaces compared with normal tissue, albeit to varying degrees. This variability in expression patterns between malignant and nonmalignant cells may in part explain some of the on-target toxicities noted with these agents. In addition, the heterogeneity of antigen expression within a given tumor may be another important consideration.[9,10]

Another key factor to be considered is rate of antigen turnover or cycling on tumor cell surface. Preclinical

PRACTICAL APPLICATIONS

- Traztuzumab deruxtecan (T-DXd) is the first antibody-drug conjugate (ADC) approved for lung cancer on the basis of activity in patients with *HER2* mutation–positive non–small-cell lung cancer demonstrated in the DESTINY-Lung01 and DESTINY-Lung02 trials.
- ADCs directed at additional targets, including TROP-2, HER3, MET, CEACAM5, and DLL2, are being clinically evaluated in a range of settings as monotherapy and in combination with other agents including immunotherapy.
- Although ADCs will likely become established as additional treatment options for lung cancer, there remains a need to develop strategies for optimal patient selection and to overcome resistance to treatment.

studies have suggested that high turnover rates of ADC targets on tumor cells may increase internalization and delivery of cytotoxic payload intracellularly, thereby increasing cytotoxic killing.[11]

The antibody component of ADCs is predominantly humanized to limit immune-mediated elimination seen with murine monoclonal antibodies. The immunoglobulin G (IgG) class is the predominant antibody backbone for several immune-based oncologic therapies, including ADCs. Further isotype subclassifications of IgG (IgG1, IgG2, IgG3, and IgG4) lead to variability in antibody half-life, constant and hinge regions, and interaction with immune effector cells via differences in Fcγ-receptor (FcγR) affinity.[12] The majority of ADCs use an IgG1 antibody, given its extended serum half-life and FcγR-binding affinity associated with complement-mediated cytotoxicity and antibody-dependent cellular cytotoxicity.[13] Alternative IgG subclasses, such as IgG3, may have greater immunogenicity[14] but are limited by a shorter half-life.[15] In comparison, IgG2 and IgG4 subclasses have apparent equivalent half-life duration to IgG1, although with limited capacity for FcγR-mediated activation of immune effector cells.[16]

Linker. The linker is a biochemical compound that connects the antibody to the cytotoxic payload. The linker serves two major roles that directly affect both toxicity profile and activity of the ADC. First, the linker maintains ADC stability within the systemic compartment, typically the bloodstream. Linker instability in this setting can lead to inappropriate or premature release of the cytotoxic payload and significant toxicity, particularly given the potent concentration of these compounds. Conversely, an effective linker must also successfully release the cytotoxic payload once the ADC is internalized by the targeted cell. Without successful delivery of the cytotoxic payload, the clinical activity of the ADC can be quite muted.[17]

Linkers are broadly categorized into either cleavable or noncleavable on the basis of the corresponding mechanism of payload release.[18] Cleavable linkers are engineered to degrade and release the cytotoxic payload on the basis of certain intracellular factors, such as acidity, glutathione reduction, or presence of lysosomal proteases leading to peptide cleavage.[19,20] Gemtuzumab ozogamicin, which was the first US Food and Drug Administration (FDA)–approved ADC, uses a hydrazine-based acid cleavable linker that is pH-sensitive,[21] while investigational agent mirvetuximab soravtansine incorporates a reducible disulfide linker.[22] Several FDA-approved ADCs including trastuzumab deruxtecan,[3] sacituzumab govitecan,[23] and enfortumab vedotin[24] are designed with peptide-based cleavable linkers.[25] Noncleavable linkers, by contrast, are formed by nonreducible bonds with amino acid residues of the connected antibody, leading to greater stability within the bloodstream.[26] The main method of payload release for noncleavable linkers is through lysosomal-dependent degradation of the entire antibody-linker complex. Of note, this lysosome-based degradation can affect payload permeability because of retention of charged amino acid residues.[27] Beyond the intracellular release of payloads, preclinical studies have suggested that release of cytotoxic payload into the tumor microenvironment may play an important role in ADC function,[28] a term known as bystander effect.[29-31]

Payload. The payload component of the ADC potentiates cytotoxic effects on the target cell after internalization and release by the linker. Earlier, ADCs incorporated more conventional chemotherapeutic agents, such as methotrexate.[32] However, these ADCs, comprising lower-potency payload compounds, showed limited efficacy compared with conventional chemotherapy delivery. More modern ADCs contain payloads consisting of higher-potency chemotherapy agents, with IC50s (denoting half maximal inhibitory concentration) in the nanomolar and picomolar range.[33] Although such concentrations could be administered through traditional systemic routes, a narrow therapeutic window limits their clinical utility. General categories of these cytotoxic payloads include antimicrotubule agents (ie, DM1) and agents that exert DNA damage such as topoisomerase I inhibitors (ie, SN-38).[34] Several of these compounds were discovered decades prior; however, their clinical potential was limited at the time by their narrow therapeutic window.

Pharmacology

A key factor in the pharmacologic profile and clinical activity of ADCs relates to the drug-antibody ratio (DAR). The DAR is the average number of payload moieties attached to each monoclonal antibody. FDA-approved ADCs have DARs

ranging from 2 to 8.[35] Although ADCs with higher DARs have expectedly greater in vitro potency, preclinical studies suggest they may be subject to more rapid hepatic clearing and carry less favorable toxicity profiles, ultimately lowering their therapeutic index.[36] ADC manufacturing may use various methods, whereby cytotoxic drug is conjugated to either lysine or cysteine residues present along the accompanying monoclonal antibody. The pattern of conjugation may be performed in a more random or controlled manner, with the former leading to variability of DAR and resulting batch effect.[37] More recent manufacturing practice incorporates controlled, site-specific conjugation at predetermined positions along the antibody, decreasing the level of heterogeneity among the final ADC product.[38]

The variability of ADC design, with the key biochemical components detailed above, can translate to differences in the pharmacokinetics (PK) and pharmacodynamics (PD). The majority of the total ADC is comprised by the antibody portion, with the PK of the ADCs, thereby significantly influenced by the properties of the antibody backbone.[39] Target-specific binding, Fc receptor–dependent recycling, and Fc effector functions—all of which are largely affected by the antibody component of ADCs—can dictate the PK and PDs of these agents. In addition to the antibody component of the ADC, other elements such as the linker, site of conjugation, and cytotoxic payload carry their own PK considerations. Conjugation status of the linker, including site of conjugation, may affect the PK of the ADCs through effects on stability while the ADC is within circulation or after internalization. More unstable linkers may lead to a faster decline in antibody concentrations while the half-life of ADCs with more stable linkers may more resemble that of unconjugated monoclonal antibodies.[40] Finally, while the cytotoxic payload component may not fully determine the PK of the corresponding ADC, its mechanism of action can affect the therapeutic index, which is important when investigating and determining appropriate dosing regimens.[41]

ANTIBODIES FOR EVERYBODY: TARGETS AND TOXICITIES OF ADCs IN LUNG CANCER

In NSCLC, additional treatment options after failure of immunotherapy combinations and after development of acquired resistance to targeted therapy in molecularly driven subtypes are clearly needed. In this context, ADCs are a rapidly emerging class of therapies that are currently being explored across a range of targets in the metastatic setting with promising early results.

ADC Targets and Therapeutics in NSCLC

Here, we briefly review the current ADC targets in NSCLC and the preliminary efficacy and toxicity of ADCs agents, excluding HER2-targeting ADCs that are discussed separately below (Table 1).

Trophoblast cell-surface antigen 2. Trophoblast cell-surface antigen 2 (TROP-2) is a glycoprotein transmembrane calcium signal transducer present in more than 50% of lung adenocarcinoma and squamous cell carcinoma, associated with poor survival.[51-53]

Datopotamab deruxtecan. Datopotamab deruxtecan (Dato-DXd) is an anti–TROP-2 ADC linked to topoisomerase I inhibitor deruxtecan via a cleavable linker. The phase I TROPION-PanTumor01 trial included an NSCLC expansion cohort where 180 previously treated patients unselected for TROP-2 expression received Dato-DXd 4, 6, and 8 mg/kg every 3 weeks. Although objective response rate (ORR) and median progression-free survival (PFS) were similar across all dose levels (25% and 6 months, respectively), treatment-emergent adverse events (TEAEs) including nausea, mucositis, and asthenia were more frequent at higher levels. It is noteworthy that interstitial lung disease (ILD) occurred in 19 patients (11%) and seemed to be dose-dependent.[23,43,54]

Dato-DXd also achieves encouraging 35% ORR and 9.5 months median duration of response in 34 NSCLC previously treated patients with actionable genomic alterations.[55] The phase Ib TROPION-Lung02 trial is evaluating Dato-DXd 4 and 6 mg/kg combined with pembrolizumab with or without platinum agents in both previously untreated and pretreated patients with metastatic NSCLC without actionable genomic alterations. In 33 response-evaluable first-line patients, the ORR was 54% (62% with doublet and 50% with triplet therapy) and the most frequent TEAEs included stomatitis and nausea. To date, no grade 4 or 5 ILD events have been considered as Dato-DXd drug-related.[4] Dato-DXd 6 mg/kg every 3 weeks is currently being explored in multiple settings, including a phase III versus docetaxel in pretreated advanced NSCLC without actionable genomic alterations (TROPION-Lung01; ClinicalTrials.gov identifier: NCT04656652). Dato-DXd is also being evaluated as first-line therapy for patients with advanced/metastatic NSCLC with PD-L1 expression $\geq$50% in the phase III TROPION-Lung08 trial comparing Dato-DXd in combination with pembrolizumab versus pembrolizumab monotherapy (ClinicalTrials.gov identifier: NCT05215340).

Sacituzumab govitecan. Sacituzumab govitecan (SG) is an anti–TROP-2 antibody linked to the topoisomerase inhibitor SN-38 by a cleavable linker. The phase I/II IMMU-132-01 basket trial included 495 patients with treatment-refractory solid tumors regardless of TROP-2 expression evaluating SG at 8, 10, 12, and 18 mg/kg on days 1 and 8 of 21-day cycles. Relevant TEAEs included gastrointestinal (nausea, diarrhea, and vomiting) and hematologic (febrile neutropenia and

TABLE 1. Clinical Data With ADCs in Lung Cancer (excluding HER2-directed ADCs)

anemia) toxicity. Dose reductions were required in 32% of patients. On the basis of these data, the dose of 10 mg/kg was selected for further development. Interestingly, the presence of homozygosity of the UGT1A1 *28 allele (*28/*28; 9.3% of patients) was associated with an almost two-fold increase in incidence of neutropenia.[23] The IMMU-132-01 study included a single-arm expansion cohort of 54 patients with previously treated NSCLC achieving an ORR of 17% and a median PFS of 5.2 months. More than 90% of the 26 assessable archival tumor specimens were positive for TROP-2 by immunohistochemistry (IHC).[54] Currently, the phase III EVOKE-01 trial is evaluating SG versus docetaxel in patients with advanced NSCLC EGFR and those with ALK wild type after immunotherapy and platinum-based chemotherapy (ClinicalTrials.gov identifier: NCT05089734).

Human epidermal growth factor receptor 3. Human epidermal growth factor receptor 3 (HER3) is a member of the HER family. Its heterodimerization with other tyrosine kinase receptors (TKR) including other HER family members and MET leads to activation of oncogenic pathways. HER3 has gained attention as an important contributor to EGFR/HER2-targeted therapy resistance.[8,56-59]

Patritumab deruxtecan. Patritumab deruxtecan (HER3-DXd) is a HER3-targeted ADC linked to deruxtecan via a tetrapeptide-based cleavable linker. A phase I trial included patients with metastatic EGFR-mutated NSCLC with previous EGFR tyrosine kinase inhibitor (TKI) therapy. Among the 57 patients receiving HER3-DXd 5.6 mg/kg every 3 weeks, the ORR was 39% and median PFS was 8.2 months. Responses were observed in patients with known and unknown mechanisms of resistance and across a multiple range of HER3 expression. Common grade $\geq$3 TEAEs included thrombocytopenia and neutropenia. ILD, although present, was an uncommon phenomenon (5%, no patients with grade >3).[45] In a cohort of 26 patients with previously treated advanced NSCLC without identified genomic diver alterations, HER3-DXd was associated with an ORR of 26.9% and a median PFS of 4.2 months.[46] An ongoing phase III trial is currently comparing HER3-DXd versus platinum-based chemotherapy in metastatic advanced EGFR-mutated patients after failure of EGFR TKI therapy (ClinicalTrials.gov identifier: NCT05338970).

MET. MET is a tyrosine kinase inhibitor that is activated through several mechanisms including amplification, exon 14 skipping mutations, and overexpression in NSCLC. These diverse mechanisms have made MET an attractive option for ADC development.[60-62]

Telisotuzumab vedotin. Telisotuzumab vedotin (Teliso-V) is an ADC composed of a c-MET–binding antibody linked to monomethyl auristatin E, a microtubule inhibitor. In a phase I trial, of 16 patients with c-Met–positive NSCLC who were treated with Teliso-V 2.4 to 3.0 mg/kg, ORR was 18.8%. The recommended phase II dose was established at 2.7 mg/kg every 21 days.[47] The LUNGMAP substudy S1400K included 28 previously treated patients with squamous histology and c-MET positive tumors. Pneumonitis was an unanticipated toxicity (two grade 5 events), and the 9% ORR failed to meet the prespecified response, leading to trial discontinuation.[63] The phase II LUMINOSITY trial aimed to identify the population best suited to receive Teliso-V. Patients with c-MET overexpression by IHC were included, and a total of 136 patients were treated with Teliso-V. In patients with nonsquamous EGFR wild-type tumors, a promising 36.5% ORR was achieved. The most common AEs included neuropathy (25%), hypoalbuminemia (21%), and nausea (22%).[48] A phase III randomized trial is currently comparing Teliso-V versus docetaxel in previously treated c-MET overexpressing, EGFR wild-type nonsquamous NSCLC (ClinicalTrials.gov identifier: NCT04928846). Teliso-V in combination with erlotinib has also been studied in 28 patients with MET-positive *EGFR*-mutant advanced NSCLC with previous EGFR-TKI achieving a promising ORR of 32% and a median PFS of 5.9 months.[64]

Carcinoembryonic antigen-related cell adhesion molecular 5. Carcinoembryonic antigen-related cell adhesion molecular 5 (CEACAM5) is a glycoprotein member of the CEA gene family and seems to promote cell proliferation and migration.[65,66]

Tusamitamab ravtansine. Tusamitamab ravtansine (TUSA) is a CEACAM5 monoclonal antibody linked to the maytansinoid warhead DM4. In a phase I clinical trial, 31 patients with metastatic solid tumors were included in the dose-escalation part. The maximum tolerated dose of 100 mg/m^2 every 2 weeks was selected for further investigation.[67] The NSCLC dose expansion evaluated two cohorts according to CEACAM5 expression by IHC. Ninety-two previously treated patients were included (64 high expressors, 28 moderate). The ORR was higher in the high-expressor cohort (20.3%). The most common grade $\geq$3 TEAEs included keratopathy (10.9%), dyspnea (11%), and asthenia (4.3%).[49] An exploratory analysis of patients with long-term treatment exposure has revealed that responses to TUSA may be durable and could not be related to CEACAM5 expression by IHC.[68] An ongoing randomized phase III study is comparing docetaxel versus TUSA in previously treated patients with metastatic nonsquamous NSCLC with CEACAM-positive tumors (ClinicalTrials.gov identifier: NCT04154956).

ADCs in Small-Cell Lung Cancer

The treatment landscape of ADCs in small-cell lung cancer (SCLC) is also evolving. Molecules such as delta-like protein 3 (DLL3), CD56, and even TROP-2 have been

evaluated as targets for ADC development.[69] Rovalpituzumab tesirine, a DLL-3–targeting ADC, failed to improve efficacy outcomes compared with topotecan or as maintenance after first-line therapy.[70,71] CD56 is the target of lorvotuzumab mertansine, an ADC with a maytansinoid payload. Its combination with first-line platinum-based chemotherapy was evaluated in a phase I/II trial. Safety was a concern, as peripheral neuropathy was present in 29% of patients and showed increased toxicity, including a higher incidence of serious infections with fatal outcomes.[72] Sacituzumab govitecan has also been analyzed in 62 patients with refractory SCLC included in the IMMU-132-01 trial. SG showed an ORR of 19%, a median PFS of 5.7 months, and a median OS of 7.1 months.[23] Ifinatamab deruxtecan (DS-7300a, I-DXd), a B7-H3–targeting ADC with a potent DNA topoisomerase I inhibitor, showed promising results in 19 patients with refractory SCLC, achieving 58% ORR. The most common TEAEs were nausea, anemia, and infusion-related reaction. I-DXd is currently being evaluated in a phase II clinical trial of patients with previously treated SCLC (ClinicalTrials.gov identifier: NCT05280470).[50]

HER2 HOMECOMING: THE JOURNEY TO TRASTUZUMAB DERUXTECAN

Alterations in the human epidermal growth factor receptor 2 (HER2, also known as ERBB2) in NSCLC have been described through three mechanisms: (1) gene mutation, (2) gene copy number gain or amplification, and (3) HER2 protein overexpression.[73-77] *HER2* mutations (*HER2*m) are typically in-frame insertions in exon 20 (96%), occur in 1%-4% of NSCLC, and are more frequent in never-smokers and in adenocarcinoma.[73-77] *HER2* gene amplification is present in 2%-5% of NSCLC. The prognostic value of *HER2* gene amplification in NSCLC is unclear.[78] HER2 protein overexpression is found in 10%-30% of NSCLC with the specific frequency depending on the cutoff score used.

Evolution of HER2-Directed Therapies

Nonselective HER2 tyrosine kinase inhibitors. Nonselective HER2 TKIs such as dacomitinib, afatinib, and neratinib have yielded inconsistent results with ORR ranging from 0% to 19% and have been associated with substantial toxicity limiting clinical utility.[79-81]

Trastuzumab with and without chemotherapy. Trastuzumab is a monoclonal immunoglobulin humanized murine antibody that binds to extracellular subdomain IV of HER2 and inhibits HER2 homodimerization, preventing HER2-mediated signaling.[82] Cappuzzo et al[83] first demonstrated activity of trastuzumab in combination with chemotherapy in a pretreated patient with *HER2* exon 20–mutant NSCLC. A small single-arm phase II study of trastuzumab monotherapy in pretreated NSCLC patients with HER2 alterations yielded disappointing results with an ORR of 0% (95% CI, 0 to 26) although the disease control rate (DCR) and mPFS were 70% and 5.2 months, respectively.[84] The EUHER2 retrospective cohort study analyzed the effects of HER2-targeted drugs given with chemotherapy in pretreated NSCLC patients with *HER2* exon 20 mutations and reported an ORR of 50.9% and mPFS of 4.8 months in the chemotherapy-trastuzumab combination group.[85] The phase IIa MyPathway basket trial assessed the activity of combination trastuzumab and pertuzumab (a recombinant humanized monoclonal antibody that inhibits dimerization of HER2 and HER3 15) in 27 patients with HER2-amplified/overexpressed NSCLC, demonstrating a modest ORR of 25.9%.[86]

ADCs in HER2 NSCLC. Two ADCs targeting HER2, first ado-trastuzumab emtansine and more recently trastuzumab deruxtecan, have been evaluated in NSCLC (Table 2).

Ado-Trastuzumab Emtansine

Structural features and chemistry. Ado-trastuzumab emtansine (also known as T-DM1) is the first ADC targeting the HER2 receptor that links trastuzumab with a tubulin polymerization inhibitor maytansinoid (DM1) via the noncleavable linker, maleimidyl 4-(N-maleimidomethyl) cyclohexane-1-carboxylate (or SMCC), to a lysine residue of the antibody.[95] The noncleavable linker improves stability in systemic circulation, and drug release occurs through lysosomal degradation of the antibody leading to intracellular cytotoxic drug release and is not expected to have substantial bystander effect.[5,95]

Clinical data in NSCLC. In a phase II study in 15 patients with pretreated *HER2* exon 20–mutant (47%) or overexpressed (53%) NSCLC, T-DM1 was reported to have limited efficacy with the mPFS and median overall survival (mOS) of 2.0 months and 10.9 months, respectively.[87] Grade 3 or 4 TEAEs were observed including thrombocytopenia (40%) and hepatotoxicity (20%). T-DM1 demonstrated modest activity in the HER2 overexpressing cohort in a phase II study that recruited 49 patients with HER IHC 2+ and 3+, with the ORR of 0% and 20%, respectively.[89] PFS was comparable between the two cohorts, 2.6 versus 2.7 months, and mOS was 12.2 versus 15.3 months, respectively.

In a subsequent phase II basket trial reported by Li et al,[88] 18 patients with pretreated *HER2*m lung adenocarcinomas were treated with T-DM1 3.6 mg/kg intravenously every 3 weeks resulting in an ORR of 44% and mPFS of 6 months. Responses were observed in those with HER2 exon 20 mutation, including two patients who had concurrent *HER2* amplification. A phase II study of T-DM1 in 22 patients with *HER2* exon 20 mutation NSCLC reported an ORR of 38.1% with a DCR of 52.4%. mPFS and mOS were 2.8 months and 8.1 months, respectively.[90] T-DM1 was well tolerated with 18.2% reported to have grade 3 thrombocytopenia. T-DM1 demonstrated promising activity in HER2 NSCLC, particularly in those who harbor *HER2* exon 20 mutation.

TABLE 2. Clinical Data With HER2-Targeting Antibody-Drug Conjugates in NSCLC

Agent	Study	Population and HER2 Alteration Type	Sample Size—Patients With NSCLC (No.)	Treatment	ORR, No. (%)	Median PFS, Months (95% CI)	Median OS, Months (95% CI)	Safety and Toxicities (%)	References

Trastuzumab Deruxtecan (T-DXd/DS-8201a)

Structural features and chemistry. [fam-] Trastuzumab deruxtecan (also known as DS-8201a or T-DXd) is a new-generation HER2-targeting ADC structurally composed of a humanized anti-HER2 IgG1 monoclonal antibody, a tetrapeptide-based cleavable linker, and a novel cytotoxic topoisomerase I inhibitor (DXd) payload.[95,96] As with TDM-1, the anti–HER-2 antibody component has the same amino acid sequence as trastuzumab; however, it has been engineered with distinctive features that potentially enhance its therapeutic activity. The linker and a self-immolative amino methylene spacer used in T-DXd reduce hydrophobicity and provide stability in the systemic circulation. The cytotoxic payload, a campthothecin topoisomerase I inhibitor, binds and stabilizes the triple complex with DNA topoisomerase 1 and DNA inducing DNA damage and apoptosis of cells. Furthermore, T-DXd exhibits a high DAR of approximately 8, almost two-fold higher than T-DM1 (DAR of 3-4), hence delivering a more potent cytotoxic payload. In addition, as a result of T-DXd's highly membrane-permeable payload, T-DXd can exert a bystander effect, thus allowing antitumor activity in heterogeneous and HER2-low tumors.[30,95]

Preclinical antitumor activity. T-DXd was evaluated preclinically across a range of HER2-expressing cell lines and patient-derived xenograft models and compared with T-DMA.[96] T-DXd had antitumor activity across a range of models with different HER2 expression levels, including KPL-4 (strong positive), JIMT-1 (moderate positive), Capan-1 (weak positive) because of its bystander effect, whereas T-DM1 was only effective against the KPL-4 model.[95,96] Pharmacokinetics were favorable with low release rates into plasma indicating its stability in the circulation.

Clinical studies of trastuzumab deruxtecan. In the phase I dose-escalation study of T-DXd, 24 patients with advanced breast and gastric or esophageal tumors received initial intravenous T-DXd between 0.8 and 8.0 mg/kg (n = 3 for each of 0.8, 1.6, 3.2, and 8.0 mg/kg doses; n = 6 for each of 5.4 and 6.4 mg/kg), and dose-limiting toxicities were assessed over a 21-day cycle.[97] The MTD of T-DXd was not reached, and the recommended phase II dosing (RP2D) was 5.4 or 6.4 mg/kg given every 3 weeks. The most common TEAEs are mild-to-moderate gastrointestinal and hematologic events. ORR was 43%, across the study including patients with low HER2–expressing tumors. PK analysis confirmed high stability of the linker payload in systemic circulation. In the phase III DESTINY-Breast03 trial, T-DXd demonstrated significantly greater efficacy compared with T-DM1 in previously treated HER2 metastatic breast cancer with 75.8% of patients alive without disease progression at 12 months versus 34.1%, with a hazard ratio for progression or death from any cause of 0.28.[98] ORR was 79.7% for T-DXd compared with 34.2% for T-DM-1. Adjudicated drug-related ILD was 10.5% with T-DXd and 1.9% in T-DM1.[98]

Trastuzumab deruxtecan in HER2 NSCLC. In the first-in-human dose-expansion clinical study investigating T-DXd, 60 heavily pretreated patients with HER2 expressing nonbreast/nongastric or *HER2*m solid tumors demonstrated encouraging antitumor activity.[91] T-DXd seemed particularly active in patients with *HER2*m NSCLC with an ORR of 72.7% and mPFS of 11.3 months.[91] This was associated with an overall acceptable safety profile, but safety signals were raised with two fatal outcomes, one of which was associated with treatment-related respiratory failure.

The phase II DESTINY-Lung01 study evaluated T-DXd in two NSCLC cohorts: HER2 overexpressing and *HER2*m tumors.[3,92] In the updated analyses reported by Li et al,[3] T-DXd 6.4 mg/kg showed robust activity in a HER2m cohort that was refractory to standard therapy, resulting in an ORR of 55% and median DoR of 9.3 months; median PFS and mOS were 8.2 months and 17.8 months, respectively. Of note, 26% of patients had adjudicated drug-related ILD with two deaths. In the subsequent DESTINY-Lung02 trial, patients with *HER2*m mNSCLC were randomly assigned to T-DXd 5.4 mg/kg or 6.4 mg/kg. Interim results demonstrated encouraging results in a heavily pretreated population, with ORRs of 53.4% in the 5.4 mg/kg cohort and 42.9% in the 6.4 mg/kg cohort.[94] There were lower frequency of adjudicated drug-related ILD (5.9% *v* 14.1%) and lower frequency of dose interruptions (13.9% *v* 30%) in the 5.4 mg/kg group.[94] The results of DESTINY-Lung01 and Lung02 trials resulted in the FDA approval for T-DXd 5.4 mg/kg dosing as new standard-of-care treatment for patients with previously treated *HER2*-mutant NSCLC. An ongoing phase III trial, DESTINY-Lung04, is evaluating T-DXd in the first-line setting for mNSCLC patients with *HER2* exon 19 or 20 mutations (ClinicalTrials.gov identifier: NCT05048797).

Despite the promising clinical results with T-DXd in the treatment resistant/refractory population, safety signals had been raised with drug-related ILD/pneumonitis. The precise pathophysiology of T-DXd–associated ILD/pneumonitis is unclear, but potential mechanisms include direct cytotoxic pulmonary injury and immune-mediated lung injury. Pooled analyses have identified potential risk factors to T-DXd–associated ILD/pneumonitis, such as higher T-DXd dose, low baseline oxygen saturation, presence of certain baseline lung comorbidities, and moderate-to-severe renal impairment.[99] Early detection of drug-related ILD/pneumonitis is key with proactive patient education and monitoring, and if drug-related ILD/pneumonitis is detected, then a multidisciplinary management approach should be adopted.[99] T-DXd treatment should be interrupted for all grade 1 and beyond ILD/pneumonitis and should not

be rechallenged if a patient experienced grade 2 or greater severity. The safety profile of T-DXd will be further defined as we obtain more real-world data on the incidence, diagnosis, and management of T-DXd–associated ILD/pneumonitis.

CONCLUSION

Advances in the fields of chemistry, pharmacology, and immunology have led to the development of ADCs that now demonstrate clinically meaningful activity in subsets of patients with lung cancer. In August 2022, T-DXd 5.4 mg/kg was approved by the FDA for patients with previously treated *HER2*m metastatic NSCLC marking the first approval of an ADC for lung cancer. This accelerated approval was based on the results from the DESTINY-Lung01 and DESTINY-Lung02 trials, which demonstrated frequent and durable tumor responses in previously treated *HER2*m metastatic NSCLC. ADCs directed at additional targets, including TROP-2, HER2, HER3, MET, and CEACAM5, are now being explored as monotherapy and in combination with other agents. As we begin to understand the nuances in ADC and tumor interactions, refine the design and chemistry of ADCs, develop strategies for patient selection, as well as toxicity management, and understand mechanisms of resistance, it is likely that ADCs will become incorporated into treatment paradigms for a broad spectrum of patients with NSCLC.

Expanding the Reach and Grasp of Lung Cancer Screening

Raymond U. Osarogiagbon, MBBS[1]; Pan-Chyr Yang, MD, PhD[2,3,4]; and Lecia V. Sequist, MD, MPH[5]

overview

Low-dose computer tomographic (LDCT) lung cancer screening reduces lung cancer–specific and all-cause mortality among high-risk individuals, but implementation has been challenging. Despite health insurance coverage for lung cancer screening in the United States since 2015, fewer than 10% of eligible persons have participated; striking geographic, racial, and socioeconomic disparities were already evident, especially in the populations at greatest risk of lung cancer and, therefore, most likely to benefit from screening; and adherence to subsequent testing is significantly lower than that reported in clinical trials, potentially reducing the realized benefit. Lung cancer screening is a covered health care benefit in very few countries. Obtaining the full population-level benefit of lung cancer screening will require improved participation of already eligible persons (the grasp of screening) and improved eligibility criteria that more closely match up with the full spectrum of persons at risk (the reach of screening), irrespective of smoking history. We used the socio-ecological framework of health care to systematically review implementation barriers to lung cancer screening and discuss multilevel solutions. We also discussed guideline-concordant management of incidentally detected lung nodules as a complementary approach to early lung cancer detection that can extend the reach and strengthen the grasp of screening. Furthermore, we discussed ongoing efforts in Asia to explore the possibility of LDCT screening in populations in whom lung cancer risk is relatively independent of smoking. Finally, we summarized innovative technological solutions, including biomarker selection and artificial intelligence strategies, to improve the safety, effectiveness, and cost-effectiveness of lung cancer screening in diverse populations.

EXPANDING THE REACH AND GRASP OF LUNG CANCER SCREENING

Lung Cancer Is Endemic

With an estimated annual global incidence of 2.2 million, 1.8 million annual deaths, and projections for a sequential increase in coming decades, lung cancer remains the oncologic public health challenge of this age.[1] Lung cancer was the most common cause of cancer deaths in men in 93 of 185 countries, and in women in 25 countries[1] and in all quintiles of the country-level global Socio-demographic Index.[2] In the United States, although the aggregate incidence of and mortality from lung cancer have sequentially reduced since the 1990s for men and the 2000s for women, the pattern of improvement is geographically heterogeneous.[3] Striking geographic disparities in per capita lung cancer statistics exist, exemplified by clusters of countries with static or rising incidence and mortality rates.[4]

In the United States, the aggregate 5-year survival with a lung cancer diagnosis is only 23% because most patients have advanced-stage disease at the time of diagnosis. Specifically, 40%-50% of patients have distant disease at diagnosis, with a 5-year survival of 7%, and 20%-30% have been diagnosed with regional disease, with a survival of approximately 30%. Only 20%-30% of patients are diagnosed with localized lung cancer when the 5-year survival is approximately 60%.[1] The aggregate 5-year survival of >90% for breast cancer, >60% for colorectal cancer, and >95% for prostate cancer can be partly attributed to the implementation of effective screening programs that promote early detection.[1] The relatively poor aggregate 5-year survival challenges us to do more to diagnose lung cancer at an early stage.

The Recent History of Low-Dose Computer Tomographic Lung Cancer Screening in a Nutshell

After the prospective observational Early Lung Cancer Action Project (ELCAP) cohort studies revealed that low-dose computer tomographic (LDCT) screening significantly redistributes lung cancer to an early stage at diagnosis,[5,6] the randomized controlled National Lung Screening Trial (NLST) corroborated the stage shift and revealed a 20% reduction in lung cancer–specific mortality and 7% reduction in all-cause mortality.[7] Initially published in 2011, the NLST led to the 2013 US Preventive Services Task Force (USPSTF) grade B recommendation, which made LDCT lung cancer

PRACTICAL APPLICATIONS

- Despite two large randomized controlled trials proving its efficacy in reducing lung cancer mortality, lung cancer screening by low-dose computer tomographic scanning has been poorly implemented, with fewer than 10% of eligible persons screened in the United States and no implementation in most countries.
- Expanding access to screening for currently eligible persons requires social policy-, organization-, provider-, and patient-level interventions.
- Eligibility criteria for screening also need to be optimized to better overlap with the persons who develop lung cancer.
- The global population of people who never smoke but develop lung cancer warrants exploration of screening approaches for people whose lung cancer risk is defined by other factors, besides smoking, as is being explored in East Asia.
- Rapidly emerging biomarker and artificial intelligence approaches have great potential to improve the safety, efficiency, and cost-effectiveness of screening but will need rigorous validation in diverse populations.

screening eligible for insurance coverage,[8] followed by the 2015 Medicare Coverage Decision that established annual LDCT lung cancer screening a covered health care benefit.[9] A gradual aggregate national redistribution of lung cancer to earlier stage at diagnosis has already become evident in the United States since 2015.[10]

Corroboration of the NLST findings by the Dutch-Belgian lung cancer screening trial (NELSON), which reported a 24% reduction in lung cancer–specific mortality in a smaller cohort, with a lower eligible age limit and less intense tobacco use history, led the USPSTF to relax screening eligibility criteria in 2021, lowering the age limit from 55 to 50 years and the cigarette smoking requirement from 30 to 20 pack-years.[11,12] The Medicare Coverage Decision of 2022 essentially adopted these changes (with an upper eligibility age limit of 77 years, rather than 80 years).[13] This is the good news.

The bad news is that lung cancer screening is proving to be a tremendous implementation challenge. By most estimates, fewer than 10% of eligible persons have participated in any lung cancer screening and a systematic review and meta-analysis of 21 studies reported adherence to subsequent screening cycles ranging from 46% to 69%, significantly lower than the 95% reported in the NLST.[14-16] However, in the first one million screened from 2015 to 2019 in the American College of Radiology (ACR) registry, adherence to annual screening was only 22.3%.[17,18] Furthermore, disparities in access have emerged. For example, there is a striking geographic mismatch between state-level per capita lung cancer mortality and location of ACR-registered screening facilities.[14,19] Of the top 10 states in the lung cancer incidence and mortality leaderboard, Kentucky is listed in the top for lung cancer screening implementation.[14] Indeed, the other nine states atop the incidence and mortality leaderboard are in the bottom half of the implementation leaderboard.[14,15] Very few countries have adopted LDCT screening as a covered health care benefit. Most countries in the European Union continue to evaluate the cost-effectiveness and feasibility of various implementation approaches.[20,21]

Implementation Challenges

Barriers to attaining the full population-level benefit of early lung cancer detection can be broadly categorized as factors that inhibit the full adoption of LDCT screening for currently eligible patients (which we refer to as the grasp of LDCT screening) and eligibility criteria limitations that prevent extension to the breadth of the population at risk (the reach of LDCT screening). Using the socioecological model of health care, factors that inhibit the grasp of lung cancer screening can be categorized into policy-, institution-, provider-, and patient-level barriers (Table 1). Because lung cancer in the United States is a disease associated with a relative socioeconomic disadvantage, the populations at greatest risk are particularly challenged by these barriers.

The US populations at greatest risk of lung cancer reside in the Mississippi Delta and the Appalachian Valley regions that include the preponderance of states that made the political decision to not expand Medicaid access under the Affordable Care Act (ACA), despite having higher proportions of uninsured and underinsured persons (public policy-level barriers).[14,15,22] These regions are largely rural, have fragmented health care delivery systems, and have the lowest density of ACR-accredited LDCT screening facilities (institutional-level barriers).[14,19] Regardless of the region, awareness of the value, risks and benefits of lung cancer screening among primary care providers, and various other specialists involved in implementing screening varies significantly (provider-level barriers).[23] Finally, persons eligible for lung cancer screening, that is, those with a history of tobacco use, are more likely to have a lower level of education and be from indigent and minoritized populations (person-level barriers).[24]

The implementation challenge is exacerbated by the triple-jump concept: Unlike other cancers for which screening is recommended (breast, cervical, colorectal), which identify

TABLE 1. Barriers and Solutions to Lung Cancer Screening Implementation Using the Socioecological Framework for Health Care

Level	Examples of Multilevel Barriers to the Reach and Grasp of Lung Cancer Screening in the United States, Solutions
Social policy	1. Health insurance coverage for lung cancer screening (a) USPSTF recommendations: 2013 and 2021. B recommendation created a pathway to insurance coverage for LDCT lung cancer screening in the United States; expanded eligibility criteria[8,12] (b) Medicare Coverage Decision: 2015 and 2022. Established lung cancer screening as a covered health care benefit; expanded coverage eligibility criteria mostly for persons 65 years or older[9,13] (c) Affordable Care Act: Eliminated co-pays for cancer screening tests, including LDCT lung cancer screening (d) Additional proposed solutions: (i) Provide health insurance coverage and consider co-pay elimination for screening-related downstream testing (ii) Extend benefits to persons in the 11 non-Medicaid expansion states[22] 2. Lack of quality standards Future solution: Establish performance benchmarks, for example, HEDIS measure for lung cancer screening.[42] 3. Social stigma related to lung cancer and smoking Public campaign to eliminate stigma associated with lung cancer.[54]
Institutional	1. Infrastructure Provision of low-dose CT screening facilities[14,19,43,44] 2. Financial structure for investment in screening facilities Assistance to build a business case for investment in early lung cancer detection infrastructure, for example, LungPLAN[45] 3. Processes (a) Candidate identification, shared decision making, feedback, promoting adherence to subsequent testing[46,47] (b) Screening team recruitment, engagement, and oversight[46,47] (c) Interdisciplinary interactivity[46,47] 4. Quality control and program effectiveness (i) Implementation structure: centralized *v* hybrid *v* decentralized[48-50] (ii) Implementation of tobacco control programs[43,46] (iii) Future: response to HEDIS measure[42]
Provider	1. Primary care provider level Awareness, engagement, support[43,46,47,53] 2. Radiologist level Support, proficiency, dedicated versus general radiology support[47] 3. Multidisciplinary specialist support Key clinician stakeholder engagement—pulmonologists, surgeons, medical and radiation oncologists, nurses, navigators; proficiency; dedication[43,46] 4. Clinician sensitivity Stigma, nihilism, cultural sensitivity[54] 5. Quality control. (i) Lung-RADS scoring system for radiologists[46,47] (ii) Future: response to HEDIS measure (primary care providers)[42]
Patient	1. Knowledge, attitudes about smoking, lung cancer, screening, health care 2. Nihilism[54] 3. Social networks and influence on beliefs and attitudes

Abbreviations: HEDIS, Healthcare Effectiveness Data and Information Set; LDCT, low-dose computer tomography; LungPLAN, Projecting Lung Assessment Needs; Lung-RADS, Lung CT Screening Reporting and Data System; USPSTF, US Preventive Services Task Force.

eligible populations solely on the basis of age (think of the long jump), participation in LDCT lung cancer screening requires determination of eligibility on the basis of age and smoking intensity (pack-year history) and quit duration (akin to the much more difficult triple jump). Indeed, when one factors in the additional structured requirements for documented shared decision making, smoking cessation counseling and (previously, but now abrogated) participation in a lung cancer screening registry to get reimbursed, lung cancer screening may be more analogous to a steeplechase. This complexity has contributed to both organization- and physician-level delays in adoption.

However, even if all eligible persons were to suddenly undergo lung cancer screening, the 2021 USPSTF eligibility criteria would still exclude a large proportion of patients who are diagnosed with lung cancer (Fig 1). In a regional cohort, of 1,858 patients with lung cancer, only 54% would have been deemed eligible for screening by the USPSTF 2021 criteria.[25] This includes 15% who never smoked, those younger than 50 years or older than 80 years, and the great preponderance of patients who either quit smoking more than 15 years earlier or develop lung cancer at lower levels of cigarette smoke exposure. Women and racial minorities, such as Black persons and Hawaiian Islanders, are at

higher risk of lung cancer at lower levels of cigarette use.[26] Indeed, when population-level race and sex-stratified lung cancer incidence are crossed with eligibility for LDCT screening (the incidence:eligibility ratio), striking differences according to race and sex become clearly evident.[27] These eligibility criteria limitations, which restrict the reach of lung cancer screening, also exacerbate preexisting race-based disparities in population-level lung cancer outcomes.[28-32] Hence, there exists the dual need to improve the implementation of lung cancer screening for those currently eligible and to improve selection criteria to accurately match the screened population to the disease population.

BUILDING A STRONGER NET: IMPROVING THE UPTAKE OF LUNG CANCER SCREENING

Building a stronger net for current lung cancer screening-eligible populations will require eliminating access barriers; improving the effectiveness of embedded tobacco cessation programs; and improving the adherence to subsequent testing recommendations, including subsequent screening tests throughout the period of eligibility. The socioecological model of health care can also be used to categorize interventions to strengthen the net (Table 1).

Policy-Level Interventions

Expansion of eligibility criteria. The USPSTF 2013 lung cancer screening eligibility criteria were derived from the NLST. It quickly became evident that the selection criteria needed to enrich a clinical trial population for persons at sufficiently high risk to prove the efficacy of LDCT screening were not necessarily optimal for selecting the full range of patients who develop lung cancer (Fig 1). By one estimate, only 20%-30% of the US population with lung cancer would have qualified for screening using the NLST eligibility criteria.[33] The USPSTF 2021 criteria modifications were designed to expand the reach of screening by lowering the age of eligibility and the intensity of tobacco exposure in the hope that this would narrow the inadvertent race- and sex-based access disparities, given that women and Black persons, two demographic populations that benefit especially well from LDCT screening,[11,28,32] are at risk of lung cancer at a young age and with less intense cigarette use.[34] However, lowering the age of eligibility from 55 to 50 years may not alleviate the race-based disparity as much as projected because of access barriers in the pre-Medicare age population that often lacks health insurance coverage.[35-40]

In addition to expanding the eligibility criteria, the 2022 Medicare Coverage Decision eliminated the requirement for participation in a defined registry and loosened the requirements for test ordering, conducting required shared decision making and smoking cessation counseling, thereby alleviating some of the organization- and provider-level barriers.[13] This should strengthen the grasp of screening among the eligible population (Table 1).

Expanding insurance coverage. The segments of the population most at risk of lung cancer also face greater challenges in accessing preventive care.[24,41] Large proportions of this population are either uninsured or underinsured (such as by Medicaid). The 11 non-Medicaid expansion states as of March 2023 (AL, FL, GA, KS, MS, NC, SC, TN, TX, WI, WY) are all in the top half of the US per capita lung cancer incidence and mortality leaderboard.[14,15,22] Most of the states also have greater than average proportions of socioeconomically disadvantaged persons who are most likely to lack employment-based health insurance. Insurance limitations also present an indirect barrier to access because of co-pays and costs associated with the diagnostic response to a positive screening test. Thus, additional policy-level interventions are needed to expand the reach and grasp of lung cancer screening, especially in the populations at greatest risk (Table 1).

Quality benchmarking. There are no existing institutional or provider quality measures for lung cancer screening, but with the support of the American Cancer Society and the American Lung Association, the National Committee for Quality Assurance has committed to developing a Healthcare Effectiveness Data and Information Set (HEDIS) measure for lung cancer screening.[42] This measure, which should become available by 2026, will incentivize health care organizations and primary care providers, the main gatekeepers to screening access, to engage in the implementation challenge.

Institution-Level Interventions

Provision of screening infrastructure. The infrastructure for lung cancer screening requires investments in facilities, equipment, and workforce.[43,44] Prevailing nihilism about lung cancer adversely influences the willingness to make these investments. However, for US institutions, the National Lung Cancer Roundtable and the ACR developed a customizable, user-friendly, financial management program, Projecting Lung Assessment Needs (LungPLAN), to help program managers make a business case to justify this investment by estimating the personalized return on investment relevant to unique aspects of the institution's service population.[45]

Successful lung cancer screening also relies on the development of processes to identify eligible candidates, invite them for the required shared decision making, and conduct tobacco cessation counseling for those who smoke. Investment in case management resources to communicate test results, development of infrastructure and processes for safe and effective decision making, and promotion of adherence to subsequent screening cycles are key features of high-functioning screening programs.[46,47] Because the

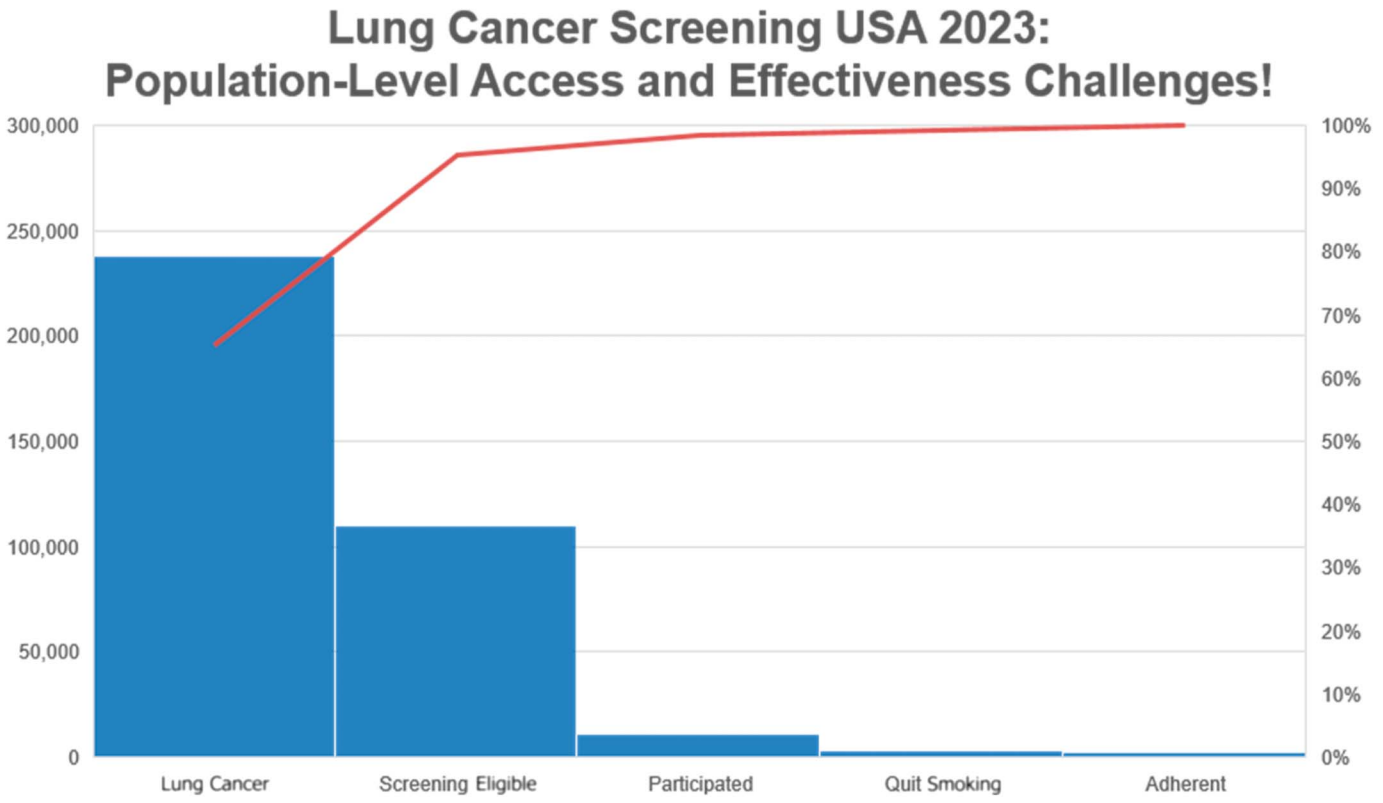

FIG 1. Estimated levels of attrition in access to lung cancer screening for patients with lung cancer, US population estimates. Estimates are based on projected 2023 US lung cancer statistics,[3] 50% screening eligibility among patients with lung cancer,[25] 10% screening participation rate,[14,15] 67% active smoking among screening participants,[25,17,18] and 22% adherence to subsequent screening cycles.[17,18]

greatest stage shift from LDCT comes with subsequent (incidence) screening cycles after the initial (prevalence) scan, the low adherence rates uncovered in the ACR registry highlight the need for a structured approach to developing lung cancer screening programs.[17,18]

Program structure. Lung cancer screening programs could be decentralized, hybrid, or centralized.[48] Decentralized models rely on individual referring providers to order screening tests and manage results. Centralized programs assume responsibility for the shared decision making, tobacco cessation management, communication of results, and promotion of adherence to subsequent management recommendations. In hybrid models, some elements of patient management are centralized while other aspects remain the responsibility of the referring provider. Adherence may be better in centralized programs.[49,50]

Complementary approaches to early lung cancer detection. Institutions can also develop processes to promote guideline-concordant management of incidentally detected lung nodules, an alternative pathway to early lung cancer detection. Such lung nodule programs are relatively agnostic to the smoking history and, therefore, bypass the implementation barriers raised by the triple-jump phenomenon.[25] They provide access to early detection to approximately five times more patients with lung cancer than LDCT screening programs, with greater demographic diversity, including more Black persons, more underinsured persons, and more patients who would not qualify for screening by the current criteria, including patients who have never smoked cigarettes.[25,51,52]

Provider-Level Interventions

Poor provider awareness of lung cancer screening availability, benefits, safety, and eligibility criteria represents another major barrier. After initial skepticism, the American Academy of Family Practice endorsed lung cancer screening in April 2021, as evidence consistently corroborated the safety and effectiveness in diverse care delivery environments.[53] Programs to avoid the stigma associated with lung cancer, including ongoing efforts to avoid the use of stigmatizing language (eg, emphasis on personhood and avoiding referring to persons who smoke as smokers), and eliminate clinician nihilism about lung cancer are likely to improve patient and provider engagement in promoting screening.[54] The multidisciplinary specialist interactions necessary for safe and effective implementation of screening can also be challenging.[46,47] Creating incentives

for the key clinicians to engage screening, such as the proposed HEDIS measure for primary care providers, will help.

Patient-Level Interventions

Campaigns to raise public awareness of the benefits, effectiveness, and safety of lung cancer screening, eliminating stigma, self-blame, and nihilism among persons whose lung cancer risk is defined by their smoking history, are important aspects of improving the grasp of lung cancer screening by increasing the likelihood of participation and adherence.[54] However, given the complexity of lung cancer screening and management of lung cancer, patients need the agency of supportive providers, care delivery systems, and social policies to fully derive the benefits of early lung cancer detection.

CASTING A WIDER NET IN ASIA: AN INTERNATIONAL CASE STUDY IN EXPANDING LUNG CANCER SCREENING ELIGIBILITY

Epidemiology and Risk Factors of Lung Cancer in Asia

Asia has the highest lung cancer disease burden, accounting for 58.5% of worldwide lung cancer incidence and 60.7% of worldwide lung cancer mortality.[55] In East Asia, the prevalence of lung cancer in people who do not smoke is high, including mostly women with lung cancer (Fig 2).[56] As a result, different screening strategies have been explored among Asian populations, which are tailored to the regional risk patterns. Significant resources have been spent on studying the increased risk of lung cancer among Asian populations who have no smoking history. Age, family history of lung cancer, history of other cancers, second-hand or passive smoking, and indoor and outdoor air pollution are likely important risk factors (Fig 3). In addition, exposure to occupational or environmental lung carcinogens, such as radon, asbestos, and silica, and pulmonary diseases, such as chronic obstructive pulmonary disease (COPD), tuberculosis (TB) and pulmonary fibrosis, are other risk factors of lung cancer.

A study from India showed that adenocarcinoma histology is significantly associated with exposure to indoor air pollution (second-hand smoke or fuel used for cooking).[57] A meta-analysis also showed that history of pulmonary TB at a young age is an independent risk factor of lung cancer, regardless of smoking history.[58] In addition, a study group from Japan also showed that second-hand smoke exposure is a significant risk factor of lung cancer.[59] In South Korea, BMI was also regarded as a predictive factor for the development of lung cancer.[60] However, no other risk factors were exclusively found in patients with lung cancer who had never smoked. This suggests the diverse impact of the different risk factors and a potential contribution from genetic factors.

Risk prediction models for people who do not smoke. The accumulated evidence of increasing lung cancer risk in people who never smoked creates a need to identify populations whose high risk is independent of smoking, who might benefit from lung cancer screening. The PLCO2014 model is analogous to the PLCO2012 model but focused on US populations who never smoked. The prediction model has seven component variables—age, education, race, BMI, COPD, personal history of cancer, and family history of lung cancer. The AUC was 0.662, but these predictors were not reparameterized to people who do not smoke.[61] Warkentin et al developed a model from a UK cohort, which included age, sex, family history of lung cancer, personal cancer history, and lung function as predictors. The AUC was 0.694. Only age and sex were reliable predictors after reparameterization.[62]

Some models are focused on Asian people who do not smoke. Wu et al[63] developed a model on the basis of Taiwanese prospective cohort data. The predictors included age, sex, BMI, family history of lung cancer, pulmonary function (maximum mid-expiratory flow), and two serum biomarkers—alpha-fetoprotein (AFP) and carcinoembryonic antigen (CEA). The AUC of 0.806 looks good, but this needs further validation. Chien et al[64] developed the Taiwanese Never-Smoker Female—Simple Questionnaire (TNSF-SQ) model, which focuses on women. Unlike previous models, they also considered gene polymorphism in addition to common predictors. The reported AUC in this model was 0.714; education level, BMI, family history of lung cancer, and COPD were regarded as significant predictors. In a prospective lung cancer screening cohort study under the framework of the Cancer Screening Program in Urban China (CanSPUC), Guo et al[65] developed a risk prediction model for individuals who did not smoke. They identified several common risk factors including age, sex, family history of lung cancer, and history of TB. The study design and results of these prediction models are summarized in Table 2.

Current guidelines and recommendations on lung cancer screening eligibility in Western populations focus mainly on people who smoke. There are considerable differences between Asian and Western patients with lung cancer; lung cancer risk factors seem to differ between the two populations (Figs 2 and 3). The implementation of lung cancer screening should be tailored to the population at risk and to the resources available to local health care systems. To further continue the discussion, a steering committee was formed with 19 lung cancer experts from 11 Asian countries across different specialties to develop consensus on the most affordable and accessible lung cancer screening approaches for Asian populations.

In their consensus statement, the committee considered several risk factors that are related to Asian populations and

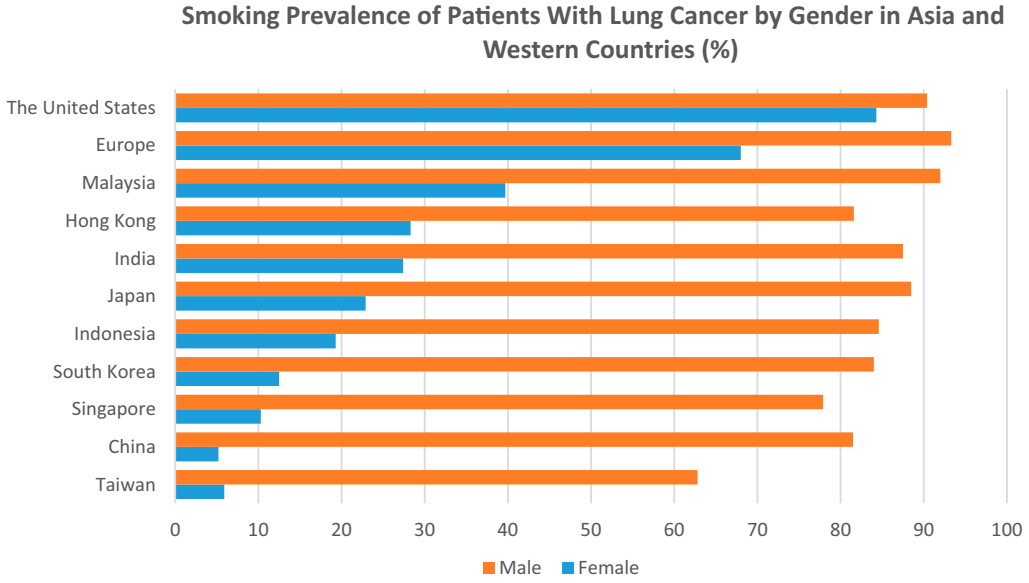

FIG 2. Smoking prevalence of patients with lung cancer by sex in Asian and Western countries.

recommended for high-risk individuals (defined by the smoking history, years since smoking cessation, and family history of cancer) to receive LDCT screening. For people who actively smoke or have quit smoking, they recommended that individuals age 50-75 years or with a smoking history of ≥20 pack-years or who quit smoking ≤15 years earlier should receive LDCT screening. For people who never smoked, individuals with a family history of lung cancer were also recommended for LDCT screening. The recommended frequency of LDCT screening was once a year for those with any screening-detected abnormality and persistent exposure to risk factors and a history of smoking ≥20 pack-years.

Lung cancer screening in people who do not smoke, but who have other risk factors. In the Taiwan Lung Cancer Screening in Never-Smoker Trial (TALENT), LDCT screening was conducted in people who never smoked, but who were, nevertheless, deemed to be at high risk for other reasons.[58] People age 55-75 years with one of the following risk factors were eligible: a family history of lung cancer in up to third-degree relatives, exposure to passive smoking, TB or COPD, cooking time-years index of 110 or greater (cooking index: 2/7 × days cooking by pan-frying, stir-frying, or deep-frying in 1 week × years cooking), and poor ventilation. The study revealed family history, especially in first-degree relatives, as the most prominent risk factor of lung cancer in people who

did not smoke.[66] The first screening round of TALENT showed a lung cancer detection rate of 2.65%, which is higher than that in NLST and NELSON. Importantly, 96.5% of the patients were detected with stage 0-I lung cancer.[66]

On the basis of TALENT, the Government of Taiwan initiated biennial nationwide LDCT lung cancer screening for high-risk patients, including people age 50-74 years with a smoking history of >30 pack-year, who agree to quit smoking, and women age 45-74 years and men age 50-74 years who have never smoked but have a history of lung cancer in first-degree relatives. Among 22,451 screened individuals from July 1, 2022, to December 26, 2022, 36% were people who smoked, 60% did not smoke but had a family history of lung cancer, and 4% had both risk factors; 160 individuals had histologically confirmed lung cancer, of whom 86.3% were in stage 0-I.[67] The preliminary results were consistent with TALENT, supporting the feasibility of LDCT screening for lung cancer in people who never smoked, who, nevertheless, had other risk factors of lung cancer. This supports expanding the lung cancer screening eligibility criteria in East Asia, where the prevalence of lung cancer is relatively high in people who do not smoke.

SHARPENING OUR TOOLS: THE NEXT WAVE OF EARLY DETECTION TECHNOLOGIES

Early Detection Biomarkers

Other possible solutions to improve the grasp and reach of lung cancer screening lie in novel technologies that use blood, breath, and image-based biomarkers. A myriad of diagnostics companies and academic groups from around the world are pursuing the development of blood-based early detection tests that examine analytes in the blood, such as DNA, RNA, exosomes, proteomics, and circulating tumor cells. However, all blood-based assays face a common hurdle: the early-stage cancers are small and secrete only a small amount of analytes that are extremely difficult to detect in peripheral blood.

DNA assays are the farthest in clinical development and are designed to detect a variety of DNA characteristics, such as specific oncogenic mutations, methylation patterns, and fragmentation patterns (Table 3). Some DNA assays are being developed to screen for multiple types of cancers simultaneously (the so-called multicancer detection assays or MCDs). To our knowledge, to date, MCD data have been presented in the context of case-control studies and single-arm prospective studies in average-risk adults, as opposed to populations at high risk of certain cancers by virtue of some clinical or demographic feature other than age.

The two largest prospective studies of MCDs presented thus far are the DETECT-A study, using an older version of the MCD assay now being developed by Exact Sciences, and the PATHFINDER study, using the MCD assay developed by Grail.[68,69] DETECT-A screened 10,000 women between age 65 and 75 years, and PATHFINDER screened a little more than 6,600 people age 50-85 years. Both studies were designed to assess the feasibility of conducting MCD screening, rather than to evaluate clinical effectiveness. In DETECT-A, nine patients were diagnosed with lung cancer

TABLE 3. Selected DNA-Based Assays to Detect Early-Stage Lung Cancer

Author	Aspect of DNA Assessed	Multicancer *v* Lung Cancer Assay	Type of Study	Commercial Name of Assay (company[ies] involved)
Jamshidi et al[77] (CCGA substudy 1)	Multiple methods explored	Multicancer	Case-control	Galleri (Grail)
Liu et al[78] (CCGA substudy 2)	Methylation	Multicancer	Case-control	
Klein et al[79] (CCGA substudy 3)	Methylation	Multicancer	Case-control	
Schrag et al[69]	Methylation	Multicancer	Prospective single-arm study	
Cohen et al[80]	Specific mutations (and proteins)	Multicancer	Case-control	CancerSEEK (Thrive); now acquired and being reworked (Exact Sciences)
Lennon et al[68] (DETECT-A)	Specific mutations (and proteins)	Multicancer	Prospective single-arm study	
Cristiano et al[81]	Fragment size	Multicancer	Case-control	Delfi
Mathios et al[70]	Fragment size	Lung cancer	Case-control	
Chabon et al[82]	Specific mutations	Lung cancer	Case-control	Lung-CLiP
Liang et al[83]	Methylation	Lung cancer	Case-control	—
Nguyen et al[84] (K-DETEK)	Methylation and fragment size	Multicancer	Prospective single-arm study	SPOT-MAS (Gene Solutions)
Gao et al[85] (THUNDER)	Methylation	Multicancer	Case-control	ELSA-seek (Burning Rock Dx)
Wang et al[86]	Fragment size	Lung cancer	Case-control	—

on the basis of abnormal blood test signal, including one patient with stage I lung cancer and two patients with stage II lung cancer (the remaining six patients diagnosed with lung cancer had more advanced-stage disease). In PATHFINDER, one patient was diagnosed with advanced lung cancer on the basis of abnormal blood test signal. While these initial results have raised concern among some that MCD tests may be less adept at finding patients with early-stage cancer eligible for surgery, it is important to remember that the current understanding of MCD testing and how to best implement it is still nascent, and many additional much larger studies are ongoing and planned. In addition, the definitive metrics by which to view the successes of MCD testing should likely take into account all cancer subtypes diagnosed by this single test rather than thinking singly about each cancer. To guide the development of MCD assays and the metrics to compare them with other screening tests, the US National Cancer Institute is launching a new cooperative group called the Cancer Screening Research Network specifically to study MCD tests and assess for cancer-specific and overall survival effects via randomized clinical trials in larger populations.

Another approach, taken by Delfi Diagnostics, is to focus on the development of a circulating tumor DNA assay for lung cancer specifically, with the concept of using a blood-based assay to guide patients not currently involved in lung cancer screening toward LDCT imaging on the basis of a high-risk blood test result. Thus far, only retrospective case-control data have been published using this assay, but there are ongoing prospective trials accruing.[70]

Because lung cancers are located proximally to exhaled breath emitted from the lungs, analysis of volatile organic compounds contained in exhaled breath is also attractive to technology developers looking to discover better ways to diagnose early-stage lung cancer.[71,72] While many mass spectrometry-based platforms have been described in this space, variables, such as comorbidities, diet, recent gum use, and recent smoke inhalation, can affect the reliability of the assay.[73,74] Interestingly, some breeds of dogs are also trained to detect the smell of lung cancer. Yet, none of these breath-based methods have been tested in large-scale clinical trials.[75,76] Details of selected publications on DNA-based assays in the development of early-stage lung cancer detection are provided in Table 3.

Radiomics and Artificial Intelligence

Finally, machine learning and artificial intelligence techniques can be applied to imaging studies to assist with lung cancer detection. Some machine learning approaches have focused on computer-aided diagnostics, which try to ensure that radiologists notice worrisome lung nodules while reading films.[87,88] A recent publication about a different application of machine learning by Mikhael et al describes the Sybil algorithm, which takes the entire volume of an LDCT scan and uses the data to predict the risk of future lung cancer, extending 6 years into the future.[89] Trained on thousands of scans from the NLST cohort, Sybil was then validated on independent LDCT cohorts from Mass General Hospital (standard US-based lung cancer screening in people with a positive tobacco history) as well as from Chang Gung Hospital

in Taiwan (consisting of people with both positive and negative tobacco history). The Sybil model can accurately predict future lung cancer risk in both of these diverse validation cohorts, raising the possibility that such a tool could be used to select people who are at the highest risk of lung cancer in future, regardless of smoking history. This is a distinct strategy from some of the clinical risk models discussed earlier, which focus on gathering known clinical and demographic risk factors for each patient. Sybil does not require clinical or demographic information, but likely integrates these and many other features visible to the computer through patterns in the computed tomography images to provide a personalized risk assessment founded on pattern recognition from thousands of previous scans. Further clinical validation in prospective studies is needed to determine the optimal strategies to implement deep learning models, such as Sybil, in lung cancer screening. In addition, as Sybil and other radiology-based deep learning models are developed and implemented, significant care will be required to ensure that the models have been tested in diverse populations and that model performance across a variety of technical image acquisition parameters has been studied.[90,91]

SUMMARY

Evidence from two large randomized trials, the NLST and NELSON, demonstrated that LDCT screening of persons at high risk of lung cancer significantly reduced lung cancer mortality. This proof of principle that lung cancer screening saves lives now challenges us to implement safe, effective, and equitable screening programs that will provide the benefit of early detection to the diverse global population of patients with lung cancer, at a cost that is acceptable to policymakers. Innovation in optimizing selection criteria (such as risk calculators); implementing supplementary pathways for early detection (such as programs to promote guideline-concordant management of incidentally detected lung nodules); expanding eligibility criteria to include additional risk factors (such as family history and genetic associations); and leveraging technology to enhance the efficiency, safety, and cost-effectiveness of screening (such as DNA-based biomarkers and artificial intelligence algorithms that can extend the value of digital imaging beyond the limitations of the human eye) are exciting solutions currently being explored. These relatively new fields of research and commercial endeavor are likely to accelerate progress into a world in which few people die of lung cancer within the next couple of decades.

A Brain, A Heart, and the Courage: Balancing Benefit and Toxicity of Immunotherapy in Melanoma

Yen-Chou Chen, MD, MBA[1,2,3]; Muhammad Jaffer, MD[4]; Lylybell Zhou, BS[1]; Javid Moslehi, MD[1]; Peter A. Forsyth, MD[4,5]; and Leslie A. Fecher, MD[6]

Overview

The overall survival of advanced melanoma has improved dramatically. Immunotherapies, specifically checkpoint inhibitors, have played a large role in this improvement. These agents have also shown benefit in the adjuvant setting, are approved for treatment of resected stage II, III, and IV melanoma, and play an evolving role in the neoadjuvant setting. Although generally well tolerated, immune-related adverse events occur and can be severe. Here we focus on some severe and potentially long term toxicities, including cardiovascular and neurologic toxicities. Our understanding of the acute and long-term toxicities of immune checkpoint inhibitors continues to evolve. Oncologists must continue to balance cancer risk and treatment-related toxicities.

INTRODUCTION

The treatment and prognosis of melanoma continues to evolve. Over the past decade, the overall survival (OS) rate of advanced unresectable disease has improved from approximately 20% at 5 years to as high as 50%.[1-3] While immunotherapies have always played a role in the treatment of melanoma, the advent of immune checkpoint inhibitors (ICIs) has increased the percentage of patients surviving and duration of survival. ICIs have come with familiar toxicities (vitiligo and thyroid dysfunction) seen with other immunotherapies such as high-dose interleukin-2. However, toxicities such as hypophysitis and other immune-related adverse events (IrAEs) are distinct. IrAEs require prompt and expert management with treatment holds and immunosuppression, typically with high-dose glucocorticoids. Although most of these toxicities have been considered acute, with the growing number of patients treated with ICI and surviving with prolonged follow-up, there is an evolving understanding of both acute and long-term IrAEs. As these agents are being investigated and used in earlier-stage disease, the balancing of toxicity with cancer risk continues to be a challenge. We propose that this should be performed on a case-by-case basis and a thorough discussion should occur with each patient, especially in the adjuvant setting.

IMMUNE CHECKPOINT INHIBITORS

ICI refers to therapeutic agents that affect the positive or negative regulatory markers of the immune system (Fig 1). Currently, all anticancer agents approved by the US Food and Drug Administration are antagonistic antibodies against negative regulators of the immune system. In melanoma, the ICI agents currently approved in the metastatic setting include ipilimumab (anti–cytotoxic T-lymphocyte–associated protein [CTLA]-4), nivolumab and pembrolizumab (anti–PD-1), atezolizumab (anti–PD-L1), and relatlimab (anti-LAG3). These agents are approved as single agents or in combination in advanced disease; ipilimumab, nivolumab, and pembrolizumab are approved as monotherapy for the adjuvant treatment of resected stage III and IV melanoma. Most recently, pembrolizumab was approved for the treatment of resected stage II melanoma. Ipilimumab has demonstrated an OS and recurrence-free survival (RFS) benefit in resected stage III melanoma; however, at higher doses (eg, 10 mg/kg), there is associated severe toxicity.[4,5] For anti–PD-1 agents in the adjuvant setting, the known benefit at this time is RFS; OS was similar for nivolumab compared with ipilimumab, and data remain immature for pembrolizumab in stage II and III.[6-8] Recent preliminary data support a role for anti–PD-1 in the neoadjuvant setting.[9] Duration of ICI treatment in melanoma is determined by treatment intent, tolerance, and response. In the advanced unresectable setting, treatment typically continues until maximal benefit or maximal toxicity, with discontinuation considered at completion of 2 years of treatment. In the adjuvant setting, treatment is for 1 year in the absence of progression and unacceptable toxicities.

IrAEs are attributed to dysregulation of the immune system, resulting in immune attack on normal organs/tissues, as CTLA-4 and PD-1 play a role in immune self-

PRACTICAL APPLICATIONS

- Immune checkpoint inhibitors (ICIs) carry potential acute and long-term toxicities.
- Cardiac and neurologic immune-related adverse events can be life-threatening and are important to recognize and manage promptly in consultation with specialists.
- Benefits of ICI therapy must be weighed against the risks, and shared decision making between the patient and the physician is recommended.

tolerance. These can be unpredictable, can affect a broad range of organs from the skin to the brain, and can range from mild to fatal.[10] The incidence, timing, frequency, and severity of IrAEs vary according to the ICI agent, dose, and if used alone or in combination.[11-13] The highest-risk regimen is the combination of CTLA-4 and PD-1 therapies with the greatest incidence in the first 3 months of treatment. The mechanisms of IrAEs continue to be investigated and overall are poorly understood. Given the variety of inflammatory cell infiltrates seen histologically, multiple mechanisms are likely.[14] Although there are data to suggest a correlation between the incidence of IrAEs and antitumor efficacy, severe toxicities are not required for benefit and may affect outcomes.[15] Acute management includes holding ICI (temporarily or permanently depending on the IrAE(s)), glucocorticoid administration, and supportive measures. Additional immunosuppressive agents may be needed depending on IrAE severity and response/control achieved with steroids. The rate of fatal toxicities is approximately 1.2%.[16] Typically, IrAEs occur during active treatment; however, there is growing understanding that the risk of toxicities continues after active dosing.[17-24] The exact duration of toxicity risk after ICI cessation is unclear but can persist for at least several months to possibly years. In addition, there is a possibility of permanent end-organ damage—best understood with ICI-induced endocrinopathies. As our understanding of the mechanisms of IrAEs increases, our understanding of their management will also.

Consideration of several factors is integral to the decision to treat with ICI: patient factors including comorbidities, functional status, pre-existing immune alteration (autoimmune conditions, transplant), and disease factors such as stage and extent of disease and potential ICI benefit. Areas of ongoing need and research include prediction models that not only predict those patients who will benefit from ICI but also those at greatest risk of toxicities. Here, we discuss some severe and long-term IrAEs to consider in the decision to treat patients with ICI. A thorough discussion of potential risks and benefits and shared decision making with the patient and the physician are recommended.

A HEART: CARDIAC TOXICITY OF IMMUNOTHERAPY

ICIs are associated with acute and chronic cardiovascular toxicities.[14,25] Acute events include myocarditis, pericarditis, vasculitis, arrhythmia, and other forms of cardiomyopathy, including Takotsubo cardiomyopathy (Fig 2).[26] Recently, more chronic issues after ICI therapy have been observed, including late-onset heart failure and atherosclerotic cardiovascular disease.[27]

ICI myocarditis is a relatively infrequent but potentially fatal IrAE, particularly among patients receiving combination ICI therapy. The incidence of ICI myocarditis has been reported to be between 0.27% and 1.14%.[28,29] However, mortality can be as high as 50%.[30] The main risk factor is combination ICI therapy. In the VigiBase, a WHO pharmacovigilance database, the combination of anti–CTLA-4 and anti–PD-1/PD-L1 antibodies was associated with a more than four-fold higher risk than either monotherapy (reporting odds ratio [OR], 4.31; 95% CI, 2.86 to 6.38).[30] Importantly, there has been an increased reporting of ICI myocarditis in the past decade, consistent with increased ICI use for cancer therapy and increased recognition of this new syndrome.[31,32] Although female sex has been identified as a risk factor for ICI myocarditis in some studies, case series of ICI myocarditis suggest higher prevalence in men.[33,34] Other risk factors for ICI myocarditis are still under investigation.

ICI myocarditis often presents with nonspecific symptoms, including chest pain, shortness of breath, palpitations, lightheadedness, and generalized weakness.[35,36] Acute coronary syndrome, pulmonary embolism, and alternative diagnoses must be ruled out. Patients with ICI myocarditis can have pre-existing coronary artery disease, which may delay or confound the diagnosis and portend a poorer outcome.[37] The median time to onset was 30 days (interquartile range, 18-60 days) after initial exposure to ICIs.[30] ICI myocarditis can occur simultaneously with other IrAEs, especially myositis. Up to one third of patients can have skeletal muscle symptoms, such as myalgia, diplopia, muscle weakness, and a myasthenia-gravis (MG)–like syndrome.[36] Importantly, severe myositis and MG-like cases can be associated with ventilatory failure because of respiratory muscle weakness. Conversely, patients who present with myositis must also be evaluated for myocarditis.[38] ICI myocarditis can be proarrhythmogenic, even when left ventricular function remains normal. Ventricular arrythmia, complete heart block, and low-voltage and pathologic Q waves are serious electrocardiographic changes and are associated with mortality.[39] On the other hand, even fulminant cases of ICI myocarditis can have preserved cardiac function. Pharmacologic and genetic models of ICI myocarditis have been generated, which recapitulate the clinical and pathologic syndrome seen in humans. These models have provided insights into

underlying pathophysiology and diagnostic and therapeutic options for patients.[40] For example, in a genetic model, activated cytotoxic CD8+ T cells targeting alpha-myosin are necessary for the development of myocarditis.[28,40-42] In addition, both Janus kinase inhibition and CTLA-4 immunoglobulin fusion protein ameliorate the disease in mice, providing biologically plausible treatment options in patients.[43]

Diagnosis of ICI myocarditis requires clinical vigilance and comprehensive evaluation, including exclusion of other cardiac diagnoses. Endomyocardial biopsy yields the most definitive diagnosis by showing infiltration of immune cells coupled with cardiomyocyte death.[44,45] Diagnosis may be alternatively made by supporting evidence and advanced cardiac imaging, including cardiac magnetic resonance (CMR).[37] Modified Lake-Louise criteria of CMR for myocarditis have been proposed to diagnose other forms of acute myocarditis (such as viral myocarditis).[46] These criteria include T1/T2 mapping and the presence of late gadolinium enhancement (LGE). However, in biopsy-proven ICI myocarditis, only 35% of patients had LGE and 26% had

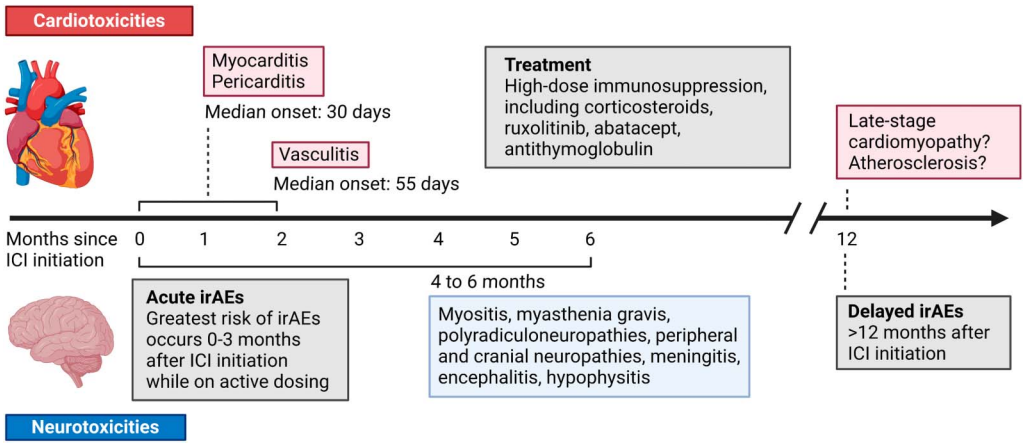

FIG 2. Toxicities timeline. ICI, immune checkpoint inhibitor; IrAE, immune-related adverse event.

elevated T2-weighted signal consistent with myocardial edema.[47] The addition of tissue characterization with T1 and T2 mapping only modestly improved diagnostic sensitivity for ICI myocarditis. In a retrospective study of clinically or pathologically diagnosed ICI myocarditis, only 48% of patients met both main T1 and T2 criteria of modified Lake-Louise criteria.[48] In addition, this study did not include relevant controls such as baseline abnormalities. In separate studies, 10%-30% of patients have abnormal CMR images even before ICI administration.[49,50] These results suggest the need for additional research to identify novel imaging tools for the diagnosis of ICI myocarditis and myocarditis.

When ICI myocarditis is suspected, ICI therapy should be held; prompt immunosuppression is recommended.[14,25] Patients should be hospitalized for diagnostic workup and telemetry monitoring. Most groups recommend high-dose corticosteroids (1-2 mg/kg of methylprednisolone every 12-24 hours) within 24 hours of the presentation. Other groups have advocated for higher doses of corticosteroids (methylprednisolone 500-1,000 mg once daily for 3-5 days) followed by 1-2 mg/kg methylprednisolone every 12-24 hours.[25] After clinical improvement, intravenous corticosteroids can be switched to an oral formulation and slowly tapered for at least 4-6 weeks. Of note, corticosteroid-resistant/corticosteroid-dependent myocarditis occurs in up to 60% of patients.[51] Case series describe multiple options of second-line immunosuppressants. Recently, the combination of ruxolitinib and abatacept has been shown to significantly reduce the mortality from 60% to 3% in patients with severe ICI myocarditis with respiratory muscle failure.[43] Although plasmapheresis has been used in case series, given the long half-life of ICIs, plasmapheresis may only remove ICIs in blood, but residual ICIs still bind with target receptors, maintaining a high receptor occupancy and proinflammatory effect.[52] Tumor necrosis factor (TNF)-alpha inhibitors are generally not recommended because of risks associated with heart failure.[53]

Baseline assessment before ICI initiation and surveillance on ICI treatment for myocarditis are other areas of investigation. Many cardiology groups recommend a baseline troponin test and electrocardiogram before ICI therapy.[25,36] However, the effectiveness of routine surveillance after initiation of ICI remains controversial. In the post hoc analysis of the JAVELIN Renal 101 Trial, a frontline study in kidney cancer, 20.4% of patients receiving ICI had an abnormal Troponin T level at baseline, whereas 13% who had a normal troponin T level at baseline developed higher levels during ICI therapy. However, in the ICI treatment group, only six myocarditis cases (of 434 patients—1.4%) were adjudicated as probable or definite ICI myocarditis.[54] Troponin level at baseline among patients with cancer can be elevated because of multiple factors including chronic kidney disease.[25,55] Additional studies are needed for more specific biomarkers associated with myocarditis.

ICI therapy can induce pericarditis (reporting OR, 3.8; 95% CI, 3.08 to 4.62) and vasculitis (reporting OR, 1.56; 95% CI, 1.25 to 1.94) (Fig 2).[30,56] The median time to onset is between 30 and 55 days, similar to ICI myocarditis.[30] Patients with pericarditis may present with sharp, pleuritic chest pain, aggravated by lying down or deep breathing and relieved by leaning forward. ICI pericarditis and pericardial effusion can result in cardiac tamponade, leading to heart failure and cardiogenic shock. The management of ICI pericarditis also includes ICI cessation and corticosteroid initiation.[25] Colchicine or nonsteroidal anti-inflammatory drugs may be added as an adjuvant treatment.[57] ICI vasculitis is overall rare but can occur in small and large vessels. Temporal arteritis, a commonly reported ICI vasculitis, can involve the aorta and its branches (reporting OR, 12.99; 95% CI, 8.12 to 20.77).[30] Patients can present with headache, monocular visual loss, diplopia, jaw claudication, and asymmetric blood pressure/pulses. The definitive diagnosis needs a temporal artery biopsy.[26] Visual loss related to ICI temporal arteritis can reach 27.8%.[30]

While much of the above discussion is regarding anti–CTLA-4 and anti–PD-1/PD-L1 therapies, recent data suggest increased risk of myocarditis in patients receiving other combinations including relatlimab and nivolumab, which carries a slightly higher incidence of ICI myocarditis (1.7%) compared with nivolumab monotherapy (0.6%).[58,59] Another consideration is the combination of ICIs with cytotoxic chemotherapy or targeted therapies, which may carry intrinsic cardiovascular risks.[60,61] In the JAVELIN Renal 101 Trial, patients were randomly assigned to avelumab (anti–PD-L1) with axitinib (anti-VEGFR inhibitor) versus single-agent sunitinib (anti-VEGFR inhibitor) alone. 7.1% of patients receiving avelumab and axitinib had major cardiovascular events, including cardiac death, myocarditis, myocardial infarction, and cerebral stroke, compared with 3.9% in the sunitinib arm.[54] Further investigation is important to understand and manage toxicities seen with ICI combinations and in ICI combined with different cancer therapies.

As patient survival improves, chronic cardiovascular toxicities, such as smoldering myocarditis, late-onset heart failure, and accelerated atherosclerosis after ICI therapy, have become emerging issues.[27] Currently, there is limited understanding about these more chronic cases. It is reasonable to consider that chronic sequalae of ICI myocarditis may evolve to cardiomyopathy.[24] In a single-center study, patients receiving ICIs had a three-fold greater risk of myocardial infarction, coronary intervention, and ischemic stroke compared with patients with cancer not treated with ICIs, with corresponding increases in aortic plaque volumes.[62] Preclinical mouse models deleting the gene for PD-1 (*Pdcd1*$^{-/-}$) or PD-L1/-L2 (*Pd-l1/2*$^{-/-}$) also showed accelerated atherosclerosis and enhanced inflammatory infiltrations in the arterial plaques.[63,64] The association between atherosclerotic disease and ICI needs to be validated in larger cohorts, but if these findings are true, these would have significant implications for the growing number of cancer survivors treated with ICI and support optimization of cardiovascular risk factors.[24] An ABCDE algorithm has been proposed to prevent cardiovascular disease in patients with breast and prostate cancers and was accepted by the National Comprehensive Cancer Network (NCCN) guideline committee for all cancer survivors.[65-67] A similar approach could be considered in patients receiving ICI. Given that recent studies implicate atherosclerosis as a late complication of ICI therapy, pre-existing cardiovascular diseases and risk factors, such as hypertension, diabetes, hyperlipidemia, and smoking, should be identified and managed.[25]

A BRAIN: NEUROTOXICITY OF IMMUNOTHERAPY

Neurologic immunotherapy-related adverse events (NirAEs) are becoming more common as an increasing number of cancers are treated with ICIs. Neurologic complications include a wide range of conditions, affecting virtually every level of the nervous system including the muscle, neuromuscular junction, peripheral nerve, plexus, spinal cord, and brain (Fig 2). To further complicate matters, more than one level of the nervous system may be implicated (eg, myasthenia gravis can occur with myositis), and although NirAEs can resemble the classical neurologic syndromes, they often have other features (eg, elevated CSF WBCs in what otherwise resembles classical Guillain-Barre Syndrome [GBS]) that may complicate the diagnosis. This is a poorly studied area, and there are no clinical trials regarding optimal treatment and limited studies regarding pathogenesis.

NirAEs occur in 1.5%-7.2% of patients treated with ICIs.[68-70] A large retrospective national database examined over 50,000 reports of immunotherapy-related adverse events, and 7.2% were NirAEs.[71] Stage III and IV melanoma incidence in the United States is estimated to be 1.5 and 0.9 per 100,000 persons, respectively; assuming that all these patients are treated with ICIs, approximately 150-600 patients with newly diagnosed melanoma per year will have NirAEs.[72,73] With stage II melanoma having an incidence of 2.4 per 100,000 persons, extending ICI therapy to this group doubles this number to approximately 300-1,200.[74] With the rapidly expanding use of ICIs, this emphasizes the need for oncologists to recognize, diagnose, and treat these syndromes quickly and the importance of consultation with neurologists.[75]

The major risk factors for NirAEs include the use of anti–CTLA-4 antibody alone or in combination with anti–PD-1/PD-L1 antibodies. One study found that the frequency of severe NirAEs was 2.8% in combination therapy, 2.2% with anti–CTLA-4, and 1% with anti–PD-1/PD-L1 therapy.[68] Among adverse events related to the recently approved relatlimab, no NirAEs were found other than hypophysitis.[58] History of an NirAE is also a risk factor. Age >60 years also confers a higher incidence of fatal NirAEs[71]; there is a suggestion that specific NirAEs are associated with specific ICIs. For example, myasthenia gravis tends to occur more often after anti–PD-1/PD-L1 treatment, whereas meningitis tends to occur more frequently after anti–CTLA-4 monotherapy. Peripheral neuropathy may occur more frequently in patients with melanoma.[76] Preexisting active neurologic diseases or neurologic autoimmune diseases predispose patients to NirAEs. ICI use should be considered carefully in patients with neurologic paraneoplastic syndromes,[77] a history of or active multiple sclerosis,[78] myasthenia gravis,[79] or amyotrophic lateral sclerosis.[80] Hence, we recommend avoiding ICIs in patients with active or severe neurologic disease and particularly neurologic autoimmune disease. Laboratory parameters have not been found to predict risk for NirAEs. One study found that patients with the *HLA-B*27:05* allele may be at an increased risk for autoimmune encephalitis triggered by atezolizumab.[81] Thus far, a specific HLA

subtype, single-nucleotide polymorphism (SNP), or other biomarker has not been found to predispose to or predict NirAEs.

The pathophysiology of NirAEs is unknown; however, both humoral and cell-mediated autoimmune mechanisms are proposed. In murine models, deletion of CTLA-4 on follicular T-helper and T-regulatory cells resulted in defective suppression of B-cell–mediated autoimmunity.[82] In another preclinical study, CTLA-4 blockade induced a CNS paraneoplastic syndrome.[83] Meanwhile, PD-1 knockout mice were used in an experimental autoimmune encephalomyelitis model and showed the expected proliferation of CNS-derived T-cell lymphocytes.[84] Nerve and muscle biopsies are rarely performed on patients with NirAEs, often because of fulminant onset and feasibility, which further limits our understanding. As pathogenic mechanisms of NirAEs are further researched, rational treatments for NirAEs will emerge.

The most common NirAEs are myositis, myasthenia gravis or other neuromuscular junction syndromes, polyradiculoneuropathies (which include GBS and other variants) and peripheral neuropathies, cranial neuropathies, meningitis, encephalitis, and hypophysitis (Table 1). The very rare neurologic paraneoplastic syndromes, such as limbic encephalitis, may occur after ICI therapy, but there are few data.[87] In general, NirAEs are very complex, difficult to recognize or diagnose, may result in permanent deficits even with prompt treatment, and require involving a neurologist as soon as possible, ideally one familiar with ICI toxicities.

There are several points about possible NirAEs that we emphasize here.

- Patients have multiple potential causes of neurologic signs/symptoms. Melanoma, as well as other tumors, can metastasize to the CNS causing neurologic symptoms. Since melanoma can metastasize to virtually any organ, it makes it very difficult to determine whether a new neurologic sign/symptom is due to an ICI toxicity or damage from another cause. Patients might have had previous therapies (targeted therapy, radiation, or surgery) that may have caused neurologic side effects. Concomitant medications, for example, corticosteroids, may induce a severe myopathy, further complicating assessment.
- The temporal relationship between the initiation of ICI and the onset of neurologic symptoms/signs can be long. Most NirAEs tend to appear within 4-6 months of initiation of ICIs. Currently, to be considered related to immunotherapy, they should generally occur within 12 months of the last infusion.[88] The occurrence of a concomitant non-NirAE and/or a robust tumor response may correlate with ICI neurotoxicity.[89]
- Consult a neurologist early and urgently if possible. Even experienced neurologists in major cancer centers find these disorders to be complex at least in part because many involve multiple areas of the nervous system (eg, muscle, neuromuscular junction, etc) at once. Shortness of breath or ventilatory issues, facial or bulbar symptoms, and ascending weakness require emergent evaluations.
- Many NirAEs are overlapping syndromes. The classifications listed in Table 1 are descriptive but not definitive. There can be a collection of symptoms and findings from several classical neurologic syndromes that may defy previous definitions. NirAEs can have several features that are atypical for a non-ICI–related GBS, for example. Non-ICI–related GBS commonly has an albuminocytologic dissociation, whereas the ICI-mediated counterpart commonly has CSF pleocytosis.[85]

Diagnostic features, key findings, and treatment recommendations are summarized in Table 2 to reflect the consensus recommendations of the NCCN, Society for Immunotherapy of Cancer, and ASCO.[14,92,93] Corticosteroids are usually used first starting at high doses for 2 weeks followed by a taper over no <4 weeks to avoid rebound of IrAEs. In many cases, these patients require hospitalization and intravenous steroids are used in conjunction with close monitoring. Corticosteroid-refractory cases are not uncommon and may require addition of other agents; discussion with a neurologist and consideration of other immunosuppressants is prudent. These include intravenous immunoglobulin, plasmapheresis (plasma exchange), rituximab (RTX), or oral immunosuppressants such as mycophenolate or azathioprine.[91] In some case reports, RTX been found to be useful for refractory cases of MG.[94] These are based on case reports or small case series and experience in treating the corresponding non-ICI–induced neurologic condition. There are no randomized studies comparing these immunosuppressant modalities to help choose the best treatment.

The prognosis is variable. Most patients recover with corticosteroids; one series found that 74% of patients had demonstrated neurologic recovery with corticosteroids alone.[95] Of all the NirAEs, ICI-induced myasthenia gravis is the most serious with an approximate 40% fatality rate, much higher than idiopathic myasthenia gravis, which is fatal in only about 2% of cases.[96,97] This may be due to the concurrent myocarditis and myositis in ICI-associated myasthenia gravis. On average, other NirAEs have lower fatality rates of 6%-12%, but these are still high compared with other IrAEs.[38] Importantly, courses of corticosteroids do not undo the antitumor effects of ICIs, but it remains unclear whether longer courses of steroids may affect cancer outcomes since ICIs dramatically suppress interferon-γ and a host of other cytokines necessary for a response.[68]

TABLE 1. Summary of the Clinical Associations, Signs/Symptoms, and Pitfalls of the Most Common Neurologic Immunotherapy-Related Adverse Events; Consult Neurology Early

Syndrome	Clinical Associations	Signs/Symptoms	Pitfalls/Notes
Myositis	Older patients	Myalgias, ocular/bulbar/limb girdle/axial muscle weakness	Approximately 25% with resp. failure; may occur with myocarditis/MG ↑ CK in approximately 33% of patients but may not correlate with severity Ddx: hypothyroid myopathy and noninflammatory myopathies
MG	Older patients and anti–PD-1/PD-L1 use	Fatigable weakness with respiratory/bulbar involvement	Urgent PFTs (FVC and NIF), consider ICU and rule out myocarditis and cardiac involvement Up to 50% may be seronegative Ddx: Lambert-Eaton syndrome
Polyradiculoneuropathies (AIDP, AMAN, Miller-Fischer, etc) and peripheral neuropathies	Melanoma and anti–CTLA-4 use	Progressive sensory/motor deficits May be rapidly ascending in GBS (ie, AIDP, AMAN, Miller-Fischer, etc)	Urgent PFTs, dysautonomia, and resp. failure can occur Ddx: chemotherapy-related neuropathy, metabolic neuropathy
Cranial neuropathies	ICI combinations	Facial weakness and hearing loss; if other cranial nerves are involved, consider LMD or Miller-Fischer variant	Ddx: LMD, chemotherapy-induced facial palsy, Miller-Fischer variant of GBS (Gq1b ABs)
Aseptic meningitis	Melanoma, young patients, anti–CTLA-4 use	Altered mental status, fever, headache, nausea/vomiting	LP to rule out infectious causes or LMD
Encephalitis	Lung cancer, anti–PD-1/PD-L1 use	Altered mental status, psychiatric disturbances, seizures, movement disorders	Ddx: metabolic encephalopathy, infectious encephalitis, PRES, rarely paraneoplastic syndrome
Hypophysitis	Anti–CTLA-4 use	Headaches, weakness, fatigue, weight loss, confusion, visual field deficit	Nonspecific symptoms, requires high clinical suspicion MRI brain fine cuts through pituitary; check serum markers of endocrine function

NOTE. Adapted from the studies by Vogrig et al[85] and Zhao et al.[86]

Abbreviations: AB, antibody; AIDP, acute inflammatory demyelinating polyradiculoneuropathy; AMAN, acute motor axonal neuropathy; CK, creatine kinase; CTLA-4, cytotoxic T-lymphocyte–associated protein 4; Ddx, differential diagnosis; FVC, forced vital capacity; GBS, Guillain-Barre syndrome; ICI, immune checkpoint inhibitors; ICU, intensive care unit; LMD, leptomeningeal disease; LP, lumbar puncture; MG, myasthenia gravis; MRI, magnetic resonance imaging; NIF, negative inspiratory force; PFT, pulmonary function test; PRES, posterior reversible encephalopathy syndrome; Resp., respiratory.

Rechallenge with ICIs in a patient who has already experienced NirAEs is controversial and must be determined on a case-by-case basis. Although NirAE-specific data are limited, studies have shown that up to 40% of patients may experience recurrent immune-related adverse events after rechallenge.[98] Patients with a high risk of cancer morbidity or mortality and minor residual neurologic sequelae stand the best chance of benefiting, whereas those with a history of severe and refractory NirAEs are poor candidates for rechallenge. Although current guidelines recommend against it, cautious rechallenge may still be considered when other treatment options are limited and the NirAEs had been minor (≤grade 2).[93]

NirAEs are uncommon but potentially fatal complications from ICIs. Early/urgent neurologic consultation for patients with symptoms/signs is critical. The current diagnostic labels for NirAEs may ease communication but are not definitive as many NirAEs involve several levels of the neuroaxis and/or have features that are distinct from classical corresponding neurologic syndromes. Balancing risks and benefits is important. In some patients with active immune-related neurologic disease or with options for alternative cancer treatments, the risks of ICIs may outweigh the benefits. Consensus treatment guidelines are useful for treatment decisions. There is a significant need for basic and clinical research in this area.

THE COURAGE: MANAGING STEROID-REFRACTORY AND LONG-TERM EFFECTS OF IMMUNOTHERAPY

Most IrAEs have been attributed to acute inflammatory changes. The greatest risk is typically in the first 3 months of treatment and while on active dosing; early IrAEs occur within the first year of treatment. IrAEs, for the most part,

TABLE 2. Summary of Diagnostic Workup, Findings, and Treatment Recommendations for the Most Common Neurologic Immunotherapy-Related Adverse Events

Condition	Diagnostic Workup	Findings	Treatment
Myositis	CK, AST/ALT, GGT, ESR, CRP, aldolase, ANA, anti-CCP PFTs Consider myositis ABs and rheumatology consultation Consider MRI of affected muscles EMG/NCS and possibly muscle Bx ECHO, EKG, and troponins Consider MRI of the brain and spine	Serum CK usually ↑, but may be normal in approximately 1 of 3 cases Myositis ABs may be positive MRI of affected limbs often shows T2 hyperintensity EMG/NCS often shows myopathic findings, and muscle Bx shows inflammatory infiltrates MRI brain and spine may show enhancement of paraspinal muscles, muscles of mastication, and/or extraocular muscles	Hold ICI Consult neurology and rheumatology Grade 2 toxicity: consider NSAIDs and oral prednisone Grades 3 and higher: consider hospitalization and IV glucocorticoids IVIG, PLEX, RTX, or INX Long-term, might consider azathioprine or mycophenolate
MG	Similar workup as myositis above Also AchR, MuSK, LRP4, VGCC, and antistriated muscle ABs Obtain repetitive nerve stimulation and consider single-fiber EMG Consider MRI brain and spine to rule out any CNS involvement	Can coexist with myositis/cardiomyopathy AB-positive in 50%-60% of cases Repetitive nerve stimulation is positive in up to 80%, whereas single-fiber EMG is highly sensitive (>95%)	Hold ICI Consult neurology and/or pulmonology Pyridostigmine and IV glucocorticoids Consider IVIG, PLEX, or RTX Avoid beta-blockers, fluoroquinolones, and IV magnesium
Polyradiculoneuropathies (AIDP, AMAN, Miller-Fischer, etc) and peripheral neuropathies	B12, folate, A1c, TSH, ESR, ANA, SPEP/UPEP, ANCA, CK Consider antiganglioside and anti-MAG ABs Consider paraneoplastic AB panel MRI of L-spine, LP EMG/NCS and possibly nerve Bx PFTs	Can be axonal or demyelinating polyneuropathy on EMG/NCS Antiganglioside and paraneoplastic ABs are sometimes positive MRI of L-spine can show nerve root enhancement LP can show albuminocytologic dissociation or lymphocytic pleocytosis	Hold ICI Consult neurology Consider pregabalin/duloxetine for symptoms of pain Initiate oral or IV glucocorticoids May also consider IVIG
Cranial neuropathies	Recommend similar serum testing to peripheral neuropathy Obtain MRI brain w/wo contrast LP	MRI brain w/wo contrast often shows cranial nerve enhancement LP with elevated protein and pleocytosis	Hold ICI Consult neurology Oral or IV glucocorticoids, eye patching to prevent corneal abrasions
Aseptic meningitis	LP (basic CSF studies, oligoclonal bands, meningoencephalitis panel, fungal panel, cytology) MRI brain and whole spine w/wo contrast EEG if seizures suspected	LP with pleocytosis/elevated protein but negative microbiologic studies with normal cytology MRI brain often shows meningeal enhancement	Hold ICI Consult neurology Oral or IV glucocorticoids until CSF viral PCR results are negative Can consider IVIG, RTX, or PLEX

(Continued on following page)

TABLE 2. Summary of Diagnostic Workup, Findings, and Treatment Recommendations for the Most Common Neurologic Immunotherapy-Related Adverse Events (Continued)

Condition	Diagnostic Workup	Findings	Treatment
Encephalitis	Similar to workup for meningitis Obtain autoimmune encephalitis and paraneoplastic panels in both serum and cerebrospinal fluid TPO ABs	MRI brain can show mesial temporal lobe enhancement in 25% of cases Anti-Hu, anti-Ma2, anti–NMDA-R, and anti-CASPR2 paraneoplastic ABs are sometimes found	Similar treatment considerations as meningitis above If no improvement despite steroids/IVIG/PLEX after 2 weeks, consider RTX
Hypophysitis	MRI brain w/wo contrast Pituitary hormone panel	Homogenously enlarged pituitary gland can be seen Anterior hypopituitarism is often seen	Consider consulting neurology and/or endocrinology Responds to corticosteroids Consider hormone replacement (levothyroxine, testosterone, etc) once adrenal axis is stable Consider NSAIDs for headache

NOTE. Adapted from the studies by Burton et al[90] and Reynolds and Guidon.[91]

Abbreviations: AB, antibody; AchR, acetylcholine receptor; AIDP, acute inflammatory demyelinating polyradiculoneuropathy; AMAN, acute motor axonal neuropathy; ANA, antinuclear antibody; ANCA, antineutrophil cytoplasmic antibodies; Bx, biopsy; CASPR2, contactin-associated protein-like 2; CCP, cyclic citrullinated peptide; CK, creatine kinase; CRP, C-reactive protein; ECHO, echocardiogram; EMG/NCS, electromyography/nerve conduction studies; ESR, erythrocyte sedimentation rate; GGT, gamma glutamyl-transferase; ICI, immune checkpoint inhibitor; INX, infliximab; IV, intravenous; IVIG, intravenous immunoglobulins; LP, lumbar puncture; LRP4, LDL receptor–related protein 4; MAG, myelin-associated glycoprotein; MG, myasthenia gravis; MRI, magnetic resonance imaging; MuSK, muscle-specific kinase; NMDA-R, N-methyl D-aspartate receptor; NSAID, nonsteroidal anti-inflammatory drugs; PCR, polymerase chain reaction; PFT, pulmonary function test; PLEX, plasma exchange; RTX, rituximab; SPEP, serum protein electrophoresis; TPO, thyroid peroxidase; TSH, thyroid-stimulating hormone; UPEP, urine protein electrophoresis; VGCC, voltage-gated calcium channel; w/wo, with/without.

have been treated as acute phenomena and were rarely long-lasting or permanent. Delayed IrAEs and chronic or long-term IrAEs are a newer concept. The first report describing long-term IrAEs was in patients with melanoma treated with single-agent ipilimumab; they reported mainly endocrinopathies, dermatologic IrAEs, and a delayed presentation of diarrhea.[17] Similar long-term toxicities were also described in patients with melanoma, renal cell carcinoma, and non–small-cell lung cancer treated with PD-1/PD-L1 inhibitors as monotherapy or in combination.[18] Chronic toxicities were more frequent with combination ICI and again included endocrinopathies, thyroid dysfunction was the most common at 10.6%. But also included were arthritis, neuropathy, dermatologic issues, and pneumonitis. They also reported radiation necrosis in 25% of patients who received cerebral radiation after starting ICI. More recently, another group reported on 118 patients with melanoma treated with PD-1 or PD-1 with CTLA-4 antibodies and included those on and off active ICI.[21] In this retrospective, multisite analysis, the incidence of delayed IrAEs, defined as an onset of >12 months from ICI initiation, was 5.3%, with the most common toxicities being colitis, rash, and pneumonitis. The majority were grade 1 and 2; however, 39% were ≥grade 3/4. There were two grade 5 delayed IrAEs (encephalitis and multiorgan IrAEs) The most common organ/sites with severe delayed toxicities included colon, liver, kidneys, and nervous system. Seventy-four percent of patients were still receiving PD-1 therapy at the onset of the delayed IrAE, 12% were within 3 months of the last ICI dose, and 14% were > 3 months from the last ICI dose.

Long-term consequences of ICI treatment may range from end-organ damage after acute IrAEs to chronic IrAEs or delayed/long-term IrAEs. IrAEs can occur after active dosing has stopped, and the end point for risk of IrAEs remains unknown, but appears to extend for at least 1 year if not longer.[17-24] At this time, definitions are still being considered/refined and are dependent on treatment duration. One group proposed the following definitions for IrAEs associated with anti–PD-1 treatment in the adjuvant setting: acute IrAEs were during treatment, delayed started after ICI cessation, and chronic persisted for >12 weeks after discontinuation.[19] They reported a delayed IrAE incidence of 43.2%, the majority in nonvisceral organs, such as

endocrine and salivary glands, joints, and skin. The majority of these chronic toxicities were grade 1 or 2 and persisted; many were symptomatic, and additional treatment was needed. Another group defined long-term IrAEs as 12 weeks to <12 months, and chronic IrAEs as >12 months since last ICI treatment.[22] This group reported long-term IrAEs in 51.9% and chronic IrAEs in 35.5%, a similar pattern involving joints, skin and endocrine glands, and a negative impact on quality of life. Risk factors for chronic IrAEs appear to overlap with risk factors for any IrAE and include combination ICI, pre-existing autoimmune conditions, and previous solid organ transplant.[18,23,24]

Two hypotheses regarding mechanisms for chronic IrAEs have been proposed by Johnson et al:[24] burnout and smoldering inflammation. Burnout is characterized as inflammation that leads to permanent damage of cells and/or organs, as seen with ICI endocrinopathies. Currently, a variety of endocrinopathies can be seen and are typically irreversible: hypothyroidism, hypopituitarism, adrenal insufficiency, and insulin-dependent DM. Less common and less well-understood endocrinopathies include pancreatic insufficiency and gonadal deficiency. Although ICI has been thought to have little impact on fertility, endocrinopathies and possible gonadal damage remain ripe for additional investigation; this has growing importance as the number of ICI-treated cancer survivors of child-bearing age/potential increases.[99] Other examples could include vitiligo and pneumonitis, with reports of persistent imaging findings at least 1-2 years from the symptom onset.[100] Neuropathies, as discussed earlier, could also fall into this category.

The other proposed mechanism is smoldering inflammation, such as in arthritis.[24] These IrAEs can flare after ICI has been stopped and appear to resemble chronic autoimmune conditions. Bowel inflammation could fall under both possible mechanisms.[101] With chronic IrAEs, the findings on imaging or symptoms may be more indicative of end-organ damage rather than ongoing inflammation. It is critical to attempt to understand if there is ongoing inflammation as this affects the decision for continuous use of steroids or other immunosuppressive agents versus monitoring. Tissue sampling in some circumstances can be of benefit in this setting.[102] The presence of chronic IrAEs also factors into a decision to rechallenge after IrAEs. If there is end-organ damage but not necessarily ongoing inflammation, rechallenge could be reasonable.

Steroid-refractory describes an inadequate response to steroids in autoimmune and other conditions, but its definition can vary on the basis of disease and organ. With respect to IrAEs, this can refer to an improvement in IrAE but ongoing dependence on high doses of steroids or limited IrAE improvement on steroids. As described above, it is possible that some steroid-refractory IrAEs may not be reflective of ongoing inflammation but rather end-organ damage. If inadequate response to initial steroid therapy is observed, rapid addition of a second-line agent is recommended to manage acute IrAEs. This is best delineated in ICI enterocolitis where anti–TNF-alpha agents are used if inadequate response is observed within the first 3-7 days.[14] For other IrAEs, second-line therapy is influenced by the typical management of the correlating autoimmune condition. Collaboration between subspecialists and oncologists is critical to determine clinical management. Immunosuppression also comes with infectious complications/risks such as opportunistic infections and other long-term risks such as cataracts, steroid myopathy, hyperglycemia and steroid-induced diabetes, decreased bone density and fracture risk, and others.[14,103,104] Although treatment of IrAEs with steroids and other immunosuppressive agents does not appear to reverse anticancer activity in the short term, the impact of prolonged steroid courses and aggressive immunosuppression should be considered.

Another approach for categorizing IrAEs is the time to resolution as the majority are expected to be temporary. Ghisoni et al[20] performed a retrospective analysis of all grade 2 or higher IrAEs in patients with lung cancer or melanoma treated at a single institution over 8 years. The incidence of at least 1 ≥grade 2 IrAE was 52.4%; 6.9% started 1 year after ICI initiation. The median duration of all IrAEs was 98 days. An IrAE duration of >6 months occurred in 35.2% and was ongoing at data cutoff or death in 40.3%. No significant correlation was found between the onset and risk of chronic IrAEs and baseline characteristics. Another report of 161 patients with melanoma treated with ICI noted that IrAEs were permanent in 41%, long-term in 9.3%, and transient in 21.1%, whereas 28.6% had no IrAEs.[23] Permanent toxicities were more common with CTLA-4 with PD-1 therapy compared with monotherapy and primarily involved the skin and endocrine glands. Treatment for long-term or permanent IrAEs was required in 32.9% of patients at ≥6 months from ICI cessation, and 2.5% of patients had a fatal IrAE.

It is important to acknowledge and counsel patients and families regarding potentially fatal IrAEs, which range from 0.4% to 1.2%.[16] As aforementioned, the toxicities that carry the highest mortality include myocarditis and NirAEs. Often, these occur early in the course of ICI treatment and rechallenge is contraindicated. A registry study from a single institution in France reported a similar grade 5 rate (1.3%) and reported very severe IrAEs (grade 4 and 5) typically seen early after ICI initiation.[105] Interestingly, these occurred with PD-1/PDL-1 monotherapy in 33 of 34 cases.[105] The ability to predict severe or life-threatening toxicities is an area of ongoing research that would have a great clinical impact. Investigation of patient factors that affect the development of IrAEs and organ specificity is ongoing.[106]

Correlations with certain SNPs and HLA types have been noted but are limited by small sample sizes and varied clinical scenarios. Recently, one group reported the presence of a germline *NLRC5* missense mutation in 9 of 13 tumors from patients who developed ICI insulin-dependent DM, not found in type 1 DM.[107]

CONCLUSION

Our understanding of the duration and extent of IrAEs and associated morbidity(ies) continues to advance. To balance known and unknown risks of ICI and known and unknown benefits, shared decision making between the treating physician and the patient is recommended. This includes a thorough discussion of potential toxicities, including fatal IrAEs, typical management strategies, and the importance of early reporting and prompt intervention. This may also include a discussion of long-term or delayed IrAEs and of unknown risks, such as the potential increased risk of atherosclerosis and infertility. In advanced unresectable melanoma, OS benefit from ICI is clearly established. In the adjuvant setting, the known benefit for adjuvant PD-1 is recurrence-free-survival. For patients with good prognosis and/or higher risk for IrAEs, long-term or severe IrAEs, it is important to balance these ICI risks with potential benefits of ICI therapy. This strategy is applicable to all histologies and treatment scenarios.

Neoadjuvant Immunotherapy in Melanoma: The Paradigm Shift

Tina J. Hieken, MD[1]; Firas Kreidieh, MD[2]; Veronica Aedo-Lopez, MD[3]; Matthew S. Block, MD, PhD[1]; Grant A. McArthur, PhD[3]; and Rodabe N. Amaria, MD[2]

Overview

Clinical stage III melanoma, defined as resectable RECIST measurable nodal disease with or without in-transit metastases, represents approximately 15% of new melanoma diagnoses every year with additional cases presenting as recurrent nodal disease following previous treatment of a primary melanoma. The standard of care for patients with resectable clinical stage III melanoma is surgical resection, consisting of therapeutic lymph node dissection and/or resection of in-transit disease and consideration of adjuvant systemic therapy and occasionally adjuvant radiation. These patients have high rates of regional recurrence and progression to metastatic disease postsurgery, highlighting the need for better treatment options. With the success of immune checkpoint inhibitors in both the adjuvant and metastatic settings, the use of these agents in the neoadjuvant setting has been an emerging area of research interest. In this chapter, we will discuss the rationale for neoadjuvant immunotherapy; review impactful clinical trials; and define response monitoring, surgical considerations, emerging therapies, and unanswered questions for neoadjuvant therapy as a recent paradigm shift in the management of clinical stage III melanoma.

BACKGROUND

Rationale for Neoadjuvant Immunotherapy

Patients with clinical stage III melanoma represent a high-risk patient population with suboptimal long-term outcomes from up-front surgery and adjuvant medical therapy.[1,2] The rationale for neoadjuvant immunotherapy stems from the concept that administration of immune checkpoint inhibitors (ICIs) while the primary tumor is still present will result in a more robust systemic antitumor immune response compared with what is seen in the adjuvant setting.[2] This phenomenon was first demonstrated preclinically[3] and then in two separate clinical trials demonstrating increased ability to generate tumor-specific CD8 T cells, resulting in improved clinical outcomes for neoadjuvant- versus adjuvant-treated patients.[4,5] With neoadjuvant therapy, the assessment of response to treatment is feasible after surgical resection, which provides useful prognostic data from tissue pathology, including intratumoral T-cell expansion, presence of tertiary lymphoid structures, and percentage of viable tumor cells.[6-9] In a pooled analysis, Menzies et al showed that pathologic complete response (pCR) correlated with improved recurrence-free survival (RFS) and disease-free survival (DFS) and suggested that pCR should be an early surrogate primary end point for clinical trials. Moreover, detecting poor response enables altering the planned adjuvant therapeutic regimen, and obtaining pCR provides the option for potentially de-escalating further treatment.[2] Neoadjuvant immunotherapy provides an opportunity to better understand the tumor microenvironment while the patient is on an active treatment[2] and allows for biomarker exploration of the applied therapy. On the other hand, particularly for surgically resectable disease, potential disadvantages of the neoadjuvant approach include disease progression delaying or precluding surgical resection and treatment-related adverse events that might delay or complicate the operation. Nonetheless, a neoadjuvant approach to high-risk stage III disease is an exciting paradigm shift supported by an increasing body of clinical data (Fig 1).

The Paradigm Shift

OpACIN-neo. The Optimal Adjuvant Combination Scheme of Ipilimumab and Nivolumab in Melanoma Patients (OpACIN)-neo trial was inspired by the preceding OpACIN trial, in which one arm evaluated neoadjuvant ipilimumab 3 mg/kg, with nivolumab 1 mg/kg resulting in a 30% pCR rate and 90% grade 3-4 toxicities. OpACIN-neo addressed the increased toxicity by altering neoadjuvant dosing of ipilimumab and nivolumab. Patients in arm A received ipilimumab 3 mg/kg and nivolumab 1 mg/kg once every three weeks for two cycles (n = 30), those in arm B received ipilimumab at 1 mg/kg dose and nivolumab at 3 mg/kg dose once every three weeks for two cycles (n = 30), and those in arm C received ipilimumab at 3 mg/kg dose once every three weeks for two cycles

PRACTICAL APPLICATIONS

- Patients with clinical stage III melanoma have high risk of disease recurrence despite up-front surgery and adjuvant systemic therapy
- Neoadjuvant therapy allows for rapid assessment of pathologic and radiographic response as well as safety data and interrogation of biospecimens collected across the continuum of treatment
- Assessment of response to neoadjuvant therapy can help personalize postoperative treatment approaches
- Any pathologic response to neoadjuvant immunotherapy seems to confer superior survival outcomes
- Neoadjuvant therapy can serve as a useful platform for new drug development and clinical trials of new agents and combinations, and can provide useful information to help inform decisions on the promise of novel therapeutics

followed by nivolumab at 3 mg/kg dose once every two weeks for two cycles (n = 26). Grade 3 or 4 adverse events were observed in 40%, 20%, and 50% of arms A, B, and C, respectively, and the pathologic response rate (defined as pCR, near pCR, and partial pathologic response [pPR]) was 80%, 77%, and 65%, respectively.[10,11] Although there was no observed association between Interferon (IFN-γ) and tumor mutation burden (TMB), Blank et al[12] reported that patients who exhibited both elevated IFN-γ and TMB had a 100% partial pathologic response rate and no recurrence at 2 years.

Nivolumab-relatlimab. The combination of nivolumab-relatlimab was used in unresectable melanoma in the RELATIVITY-047 trial, and the same agents were used in the neoadjuvant setting in patients with resectable clinical stage III or oligometastatic stage IV melanoma.[13,14] Patients received two cycles of neoadjuvant nivolumab and relatlimab at fixed doses of 480 mg and 160 mg, respectively, every 4 weeks, followed by surgical resection, and then 10 doses of adjuvant nivolumab-relatlimab combination. The trial included 30 patients treated with a pCR rate of 57% and pathologic response rate of 70%. No grade 3 or 4 adverse events were observed in the neoadjuvant setting. The radiologic response rate was 57%. The 1- and 2-year RFS was 100% and 92%, respectively, for patients who had any pathologic response, and 88% and 55%, respectively, for patients who did not exhibit a pathologic response (P = .005).[14] The authors reported a significantly greater quantity of CD8+ tumor-infiltrating T cells, increased tumor cell PD-L1 expression, higher rate of T-cell clonality, and higher levels of lymphoid markers among patients who responded versus nonresponders.[15,16]

SWOG S1801. The Southwest Oncology Group (SWOG) S1801 trial was a randomized phase II trial that compared adjuvant and neoadjuvant pembrolizumab among patients with clinical stage III or oligometastatic, resectable stage IV melanoma. Patients who received adjuvant therapy underwent surgery first followed by 18 doses of pembrolizumab at a dose of 200 mg every 3 weeks (n = 159) while patients who received neoadjuvant therapy received three doses of preoperative pembrolizumab followed by surgery and then 15 doses of adjuvant pembrolizumab (n = 154). Patients were required to undergo planned surgical resection; therapeutic lymph node dissection (TLND) for the stage III patients, regardless of response to neoadjuvant therapy; and no de-escalation of surgery occurred. At 2 years, event-free survival (EFS), defined as disease progression or toxicity that prevented a participant from having a surgery, adjuvant therapy not initiated within 84 days of surgery, postoperative relapse, or death due to any cause, was 72% and 49% for neoadjuvant and adjuvant pembrolizumab, respectively. Treatment-related adverse event rates were similar among both treatment arms. On local review, 21% of neoadjuvant participants with submitted pathology reports achieved a pCR.[5]

Neoadjuvant Immunotherapy Response Assessment

Objective response assessment. Neoadjuvant trials enrolling patients with RECIST 1.1 measurable disease allow for the assessment of both radiographic and pathologic response. In clinical trials, outcome measures are based on image-based trial end points and include objective response rate, progression-free survival, and EFS. EFS is often defined as time from random assignment to any of the following events: progression of disease that precludes surgery, local or distant recurrence, or death due to any cause. Analogous to DFS in the adjuvant setting, EFS assessment in the neoadjuvant setting accounts for early progression to nonsurgically treatable diseases.[17] Clear guidelines exist for pathologic response assessment on the basis of the 2016 and 2017 International Neoadjuvant Melanoma Consortium (INMC) meetings, which defined pCR as the "absence of residual invasive cancer … after evaluation of the completely resected specimen." Other pathologic substages, including near pCR (>0% but ≤10% viable tumor), pPR (>10% to ≤ 50% viable tumor), and no pathologic response (pNR; >50% viable tumor), have also been widely used, which depend on the calculation made by the reporting pathologist on the total tumor area affected at baseline.[7] Some studies use major pathologic response (MPR) to denote both patients with pCR and near pCR, and any

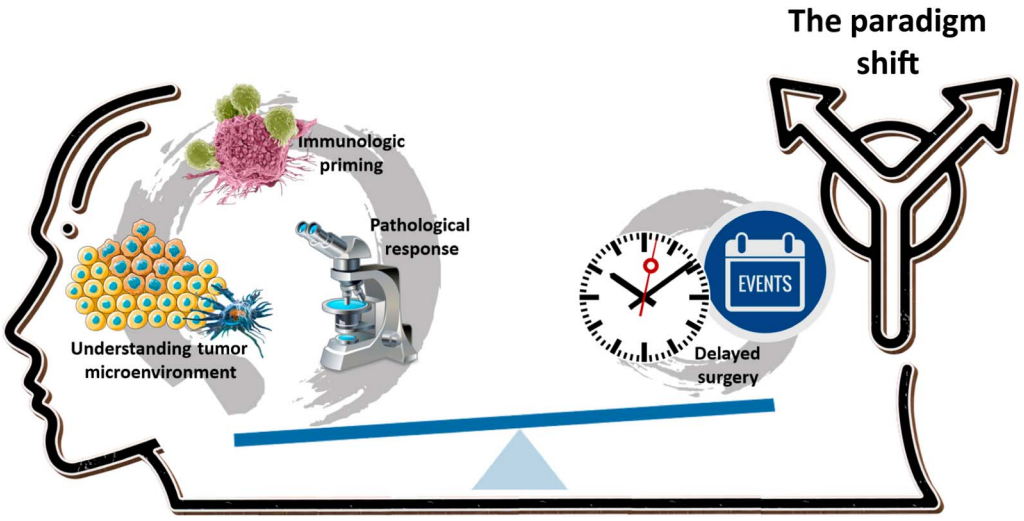

FIG 1. The paradigm shift: potential advantages of neoadjuvant immunotherapy.

pathologic response is defined as patients with pCR, near pCR, and pPR.

Historically, the critical end point correlating with durable clinical efficacy emphasized pCR on the basis of chemotherapy trials in patients with breast cancer.[18-20] This phenomenon also appears important in the context of neoadjuvant BRAF/MEK therapy. In the INMC pooled analysis, in patients with stage III melanoma, achieving only a pCR after neoadjuvant BRAF/MEK inhibitor therapy, but not a pPR, was associated with improved RFS[8,21,22] with a median follow-up of 20.9 months. Patients who had near pCR or pPR exhibited outcomes that were similar to nonresponders. Data from neoadjuvant immunotherapy suggest that any pathologic response is associated with favorable durable clinical outcomes.[8,11,23,24] Although few patients with a pCR to immunotherapy experience recurrence, recurrences have also been observed among patients with a pCR to targeted therapy.[8,16] Additionally, this trend of any pathologic response correlating with improved clinical outcomes after neoadjuvant immunotherapy was paralleled in studies of other malignancies, including lung cancer, head and neck squamous cell carcinoma, and Merkel cell carcinoma,[25-27] further supporting that a pCR, while preferable, is not essential in the setting of neoadjuvant immunotherapy.

Potential prognostic biomarkers. The relationship between pathologic response and preoperative clinicopathologic traits is being investigated in several studies, and collection of serial biospecimens is strongly encouraged. On the basis of the OpACIN-neo study showing improved outcomes in patients with high baseline IFN-γ levels, the DOMINI study was designed to ascertain response of domatinostat, nivolumab, and ipilimumab in IFN-γ low and IFN-γ high stage III melanoma. Domatinostat is a selective class I histone deacetylase inhibitor that can enhance IFN-γ expression, and the goal was to convert tumors that have low IFN-γ expression pretreatment to a high IFN-γ expressing phenotype, thus potentially enhancing the tumor response.[28] Single-agent nivolumab was highly effective in patients with baseline high IFN-γ expression while in patients with low IFN-γ expression, even triplet therapy was not sufficient to improve pathologic outcomes. Although this study failed to show improved outcomes with the experimental agent, it highlights an innovative biomarker-based trial design to optimize the treatment approach depending on baseline tumor characteristics.[16]

Surgical Considerations

The surgical oncologist plays a pivotal role in the multidisciplinary team caring for patients with high-risk stage III melanoma. Surgical oncologists are uniquely suited for assessing resectability that involves both the technical feasibility of operation (defining disease extent, describing nodal matting, and fixation to adjacent structures) and the likelihood of meaningful clinical benefit from an operation. Surgeons are therefore critical in determining appropriate patient selection for this approach as well as for ensuring cohesion from presentation through neoadjuvant treatment to response assessment, surgery, postoperative care, and outcomes.

Impact of neoadjuvant treatment on operative management and perioperative care. Initial concerns raised around the neoadjuvant approach centered on loss of disease control, potentially precluding curative surgical resection of disease. Evidence to date suggests that regional disease progression to unresectability has not been an issue. Instead, approximately 5% of patients enrolled in neoadjuvant trials with stage III disease on initial assessment have been found to progress to distant metastatic disease at restaging imaging following neoadjuvant systemic therapy before surgery,

sparing this small percentage of patients an unnecessary operation.[8,29] A second theoretical drawback to neoadjuvant therapy might be a negative effect on the technical conduct of the operation. This has been evaluated prospectively with structured surgeon surveys within the NeoACTIVATE neoadjuvant trial (ClinicalTrials.gov identifier: NCT03554083) for high-risk resectable stage III melanoma testing combinatorial neoadjuvant therapy regimens on the basis of BRAF status.[30] In this study, patients had a median largest lymph node size of 4 cm, a median three affected nodes, and 50% had fixation to adjacent structures at presentation. The investigators found that while surgeons most often assessed the degree of difficulty of operation as greater than the usual TLND, the operation was deemed more difficult than baseline impression in only 17% of cases and easier in one quarter of cases. As different neoadjuvant regimens are tested in patients with disease that may be cured with an operation, it is critical to evaluate the impact of neoadjuvant treatment on the technical conduct of the operation. As such, these survey instruments have been adapted and incorporated recently into the INMC guidelines.[29] A third consideration is the effect of potential irAEs on time to operation (surgical delay), perioperative management, and postoperative complications. The treatment team needs to be aware of irAEs as well as the likely chronology for emergence of the most frequent and impactful irAEs to inform appropriate preoperative evaluation and perioperative management. Assessment for endocrine, liver, and cardiac abnormalities should be done preoperatively. Patients on systemic steroids for an irAE should be deferred for operation until they are improving (grade 1), and steroids are being tapered. Steroid treatment is not a contraindication to proceeding to operation but does incrementally increase the risk of wound complications.[29] Additionally, the team needs to consider that some irAEs develop at later time points[31-33] (in recently reported neoadjuvant trials, approximately one third of irAEs emerge beyond week 12) and may confound perioperative management such as when hypotension secondary to hypophysitis may emerge in the postoperative period and erroneously be attributed to sepsis or other postsurgical cause.[34]

Response assessment before operation. Following completion of neoadjuvant therapy, the primary purpose of preoperative imaging is to assess for distant metastatic spread of melanoma, as systemic progression of disease would render a TLND futile from the standpoint of cancer control. Suspicious new lesions should be biopsied whenever feasible, as immunotherapy-related changes—particularly growth of distant lymph node due to expansion of lymphocytes—can resemble metastatic disease on both computed tomography and positron emission tomography imaging.

In addition to evaluating for distant metastases, preoperative imaging provides information on response of the tumor-positive lymph node(s) to neoadjuvant treatment. However, it is critical to note that radiographic responses (RECIST or iRECIST) frequently do not correlate with pathologic responses seen at the time of the operation. For example, in the OpACIN-neo study testing neoadjuvant ipilimumab and nivolumab, the radiographic response rate (CR + PR) per RECIST 1.1 was 52%, while the pathologic response rate (pCR, near pCR, or pPR) was 74%.[11] These results demonstrate that it is entirely possible for a patient to have stable disease or even progression radiographically and yet still have a favorable pathologic response to neoadjuvant therapy, thus highlighting the critical role for surgical resection after completion of neoadjuvant therapy.

In short, response assessment after neoadjuvant therapy is critical for identifying patients who will not benefit from TLND because of either distant disease progression or rapid regional progression involving encasement of critical structures. However, radiographic response alone should not serve as a surrogate for pathologic evaluation of the lymph node basin as a predictor of the efficacy of neoadjuvant treatment.

Tailoring treatment. As mentioned earlier, one of the many compelling advantages of neoadjuvant immunotherapy for patients with surgically resectable high-risk stage III melanoma is the potential opportunity to tailor treatment on the basis of response. De-escalation of the extent of TLND has been occurring before the availability of efficacious systemic therapies to test in the neoadjuvant setting, largely because of significant improvements in cross-sectional imaging over time. Thus, before operation, surgeons can now more accurately define the anticipated extent of nodal disease. Current cancer surgery guidelines endorse less extensive TLNDs for patients with melanoma, including two- versus three-level axillary dissection and superficial (inguinofemoral) versus radical (inguinofemoral plus external iliac and obturator) lymph node dissection for appropriately selected patients.[35] With neoadjuvant therapy, further de-escalation of the extent of operation for clinical stage III melanoma, on the basis of treatment response, is now being explored. The MemaLoc substudy within the OpACIN-neo trial evaluated pathologic response in the index lymph node (defined as the largest metastatic node) and the remainder of the lymph nodes in the TLND specimen in 12 patients and reported concordance in all cases.[36] The results of this substudy and the high pathologic response rates seen in OpACIN-neo supported opening the study's PRADO extension cohort to further explore de-escalation of both the surgical and adjuvant therapies on the basis of response to neoadjuvant treatment. Primary end points of PRADO included pathologic response rate and 24-month RFS for patients with a MPR ($\leq$10% viable tumor) treated per protocol that omitted TLND and adjuvant therapies for this patient group, on the basis of the potential of neoadjuvant therapy to eradicate

subclinical micrometastatic disease and the durable responses seen after cessation of immunotherapy among responders to ICI for advanced disease.[34] The index lymph node was marked at baseline with a magnetic, radioactive, or sonographically visible marker and retrieved at the first operation in 90 of 94 patients, which included retrieval of >1 lymph node (range, 2-7) in 40%, highlighting the feasibility of this approach. Among 60 patients with a MPR treated with limited surgery, after a median follow-up of 28 months, there were four regional recurrences, all among patients with two or more FDG-avid nodes on baseline scans, resulting in a failure to meet the primary RFS end point (null hypothesis not rejected in case of >1 recurrence). These four patients proceeded to delayed TLND, and one patient later developed a distant recurrence. Thus, although attempts are being made to de-escalate treatment on the basis of neoadjuvant response, this is still experimental and further work must be done to adequately identify patients eligible for de-escalation approaches.

Neoadjuvant Therapy Beyond PD-1, Anti–Cytotoxic T-Cell Lymphocyte-4, and Lymphocyte Activation Gene-3 (LAG-3) Checkpoint Inhibitors

Despite the excellent efficacy of single-agent anti-PD01, anti–PD-1 therapy in combination with either anti–cytotoxic T-cell lymphocyte-4 (CTLA-4) or anti–LAG-3,[11,14,23,24] a significant number of patients do not respond; to address this, new treatment options are being investigated in the neoadjuvant setting. One major advantage of the evaluation of novel combination therapies in the neoadjuvant setting is the use of pathologic response as a trial end point that provides rapid evaluation on efficacy and facilitates testing of multiple hypotheses, even in the one trial.

Oncolytic Viruses

Talimogene laherparepvec (T-VEC) is a genetically modified oncolytic herpes simplex virus type 1 used for unresectable IIIB-IVM1 melanoma.[37] A phase II study compared neoadjuvant T-VEC followed by surgery to surgery alone in patients with resectable stage IIIB-IVM1a melanoma. One hundred fifty patients were enrolled and divided into two arms. In total, 17.1% of patients achieved a pCR after neoadjuvant treatment with T-VEC; however, 19 (25%) patients in the T-VEC arm did not undergo surgery, primarily (58% of cases) because of progressive disease.[38]

A phase II clinical trial (ClinicalTrials.gov identifier: NCT04330430) is currently underway to assess the effectiveness of a combination treatment of T-VEC and nivolumab in the neoadjuvant setting for patients with stage IIIB-IVM1a melanoma. Participants will receive four intralesional injections of neoadjuvant T-VEC, in combination with nivolumab every two weeks from cycle 2. This trial is expected to be completed by the end of 2023. Another phase II trial (ClinicalTrials.gov identifier: NCT03842943) is evaluating the use of T-VEC in combination with an anti–PD-1 treatment in patients with stage III disease. Twenty-eight patients will be recruited for the study and will receive T-VEC injections into palpable lymph nodes every three weeks for six months or until complete response of target tumors concomitant with pembrolizumab every three weeks for six months and adjuvant pembrolizumab for one year following surgery.

New oncolytic viruses are also being evaluated in the neoadjuvant setting. A phase Ib trial is evaluating the use of recombinant human GM-CSF herpes simplex virus intratumoral injection (OrienX010) in combination with the recombinant humanized anti–PD-1, toripalimab, as a neoadjuvant treatment for patients with resectable stage III and IV (M1a) melanoma.

BRAF-Targeted Therapy

Several studies have evaluated combined BRAF and MEK inhibition alone or in combination with immunotherapy. Two different phase II clinical trials have studied neoadjuvant dabrafenib plus trametinib followed by the same adjuvant therapy.[21,22] Long et al reported the outcomes of a single-arm clinical trial involving 35 patients with resectable stage IIIB-C melanoma receiving 12 weeks of neoadjuvant and 40 weeks of adjuvant dabrafenib and trametinib. All patients achieved an imaging response, and 49% of them had a complete pathologic response.[22] The second study compared neoadjuvant plus adjuvant dabrafenib and trametinib versus standard-of-care physicians' choice in patients with resectable III or oligometastatic stage IV melanoma randomly assigning patients 2:1 favoring the targeted therapy arm. Fourteen patients received 8 weeks of neoadjuvant and adjuvant treatment with trametinib and dabrafenib while seven patients were randomly assigned to the standard-of-care physicians' choice arm. pCR was observed in 58% of patients who received neoadjuvant therapy with dabrafenib and trametinib. Although this was a small study after a median follow-up of 18.6 months, 71% of patients treated with targeted therapy were alive, whereas no patients of the standard-of-care group survived. The median EFS was 19.7 months in the treatment arm compared with 2.9 months in the standard-of-care arm.[21]

BRAF Therapy and Immunotherapy

Triple therapy of neoadjuvant anti–PD-1 and BRAF plus MEK inhibitors has been recently presented at ASCO 2022. In the NeoTrio study, 60 patients with stage III melanoma were randomly assigned to one of three different arms and received 6 weeks of neoadjuvant treatment. Participants in the ALONE arm received two courses of pembrolizumab, the SEQ arm received one week of dabrafenib and trametinib followed by two cycles of pembrolizumab, and the CON arm received pembrolizumab concomitant with dabrafenib and trametinib. After surgery, patients had 46 weeks of the same assigned treatment to complete a total of

12 months. Patients in the CON arm had the best outcomes, with 80% achieving a pathologic response and 50% pCR. The ALONE and SEQ arms had 30% and 20% pCR, respectively. After a median follow-up of 20 months, none of the patients who achieved pCR in the ALONE and SEQ arms had recurrence while only one in the CON arm showed progressive disease.

Two clinical trials, NeoPele (ClinicalTrials.gov identifier: NCT04207086) and NeoACTIVATE (ClinicalTrials.gov identifier: NCT03554083), are investigating the combination of immunotherapy and targeted therapy as neoadjuvant treatment for resectable melanoma. The NeoPele is a phase II, single-arm clinical trial, currently exploring combined lenvatinib and pembrolizumab. Lenvatinib is a potent multiple tyrosine kinase inhibitor that selectively suppresses vascular endothelial growth factor and fibroblast growth factor receptors.[39] This dual inhibition can affect T cells by decreasing the expression of PD-1, CTLA-4, and Tim-3.[40] Furthermore, combination therapy with lenvatinib and anti–PD-1 significantly inhibited tumor growth in murine models associated with increased influx of T cells, including $CD8^+$ T cells.[41] This trial will enroll 40 patients with histologically confirmed diagnosis of resectable stage IIIB, IIIC, or IIID cutaneous or unknown primary melanoma (excluding in-transit or satellite metastases). Patients will receive neoadjuvant pembrolizumab and lenvatinib for 6 weeks and, after surgery, adjuvant pembrolizumab alone for 46 weeks. In addition, the study NeoPeLeMM (ClinicalTrials.gov identifier: NCT05545969) and the study NCT04622566 are investigating this combination as neoadjuvant treatment in patients with resectable mucosal melanoma.

The NeoACTIVATE trial (ClinicalTrials.gov identifier: NCT03554083) is a nonrandomized phase II trial that enrolled 30 patients with high-risk stage III melanoma in two arms. Patients in arm A received neoadjuvant vemurafenib and cobimetinib for up to three cycles associated with atezolizumab starting from the second cycle while patients in arm B received atezolizumab and cobimetinib. Following TLND, adjuvant atezolizumab was administered every 3 weeks for up to eight cycles in both groups. These two arms of the study have completed accrual, with results expected soon.

Combinations Targeting Multiple Immune Checkpoints

Targeting multiple immune checkpoint receptors has shown improved efficacy in different trials (see above). Tiragolumab is a monoclonal antibody that targets T-cell immunoglobulin and immunoreceptor tyrosine-based inhibitory motif domain (TIGIT), an inhibitory receptor found on T cells and natural killer cells. TIGIT activates an inhibitory signaling pathway in T cells by suppressing the phosphoinositide 3 kinase/mitogen-activated protein kinase signaling pathways.[42] Given promising data on the combination of tiragolumab with atezolizumab, in patients with metastatic non–small-cell lung cancer, this combination is being pursued in NeoACTIVATE arm C. Patients in arm C will receive neoadjuvant atezolizumab and tiragolumab every 21 days for up to four cycles followed by surgery and adjuvant atezolizumab.

The Morpheus-Melanoma trial (ClinicalTrials.gov identifier: NCT05116202) is currently underway to evaluate efficacy, safety, and pharmacokinetics of different combinations simultaneously that may enhance antitumor activity, including inhibitors of LAG-3, TIGIT, and PD-1. Cohort 1 will include patients with stage III melanoma with clinical lymph node metastasis. Patients will be randomly assigned to receive neoadjuvant treatment for 6 weeks in one of three experimental arms or a comparator arm of combined ipilimumab and nivolumab. The three experimental arms will study RO7247669, which is a bispecific anti–PD-1 and anti–LAG-3, atezolizumab plus tiragolumab, and RO7247669 plus tiragolumab. The simultaneous evaluation of several combinations in the Morpheus-Melanoma trial is a promising approach to accelerate the development of novel neoadjuvant therapies in patients with resectable melanoma.

Unanswered questions. Despite the intriguing clinical data on neoadjuvant therapy for clinical stage III melanoma, a number of unanswered questions remain.

1. What is the right choice of agent(s) for neoadjuvant therapy? Thus far, robust data exist for neoadjuvant single-agent anti–PD-1, ipilimumab and nivolumab, and nivolumab and relatlimab[5,10,11,14] with emerging data on triplets and injectable agents. These regimens have not been compared head-to-head; thus, selecting the best regimen poses a challenge. Ultimately, the choice of regimen will be determined by patient and tumor characteristics. Although there is growing evidence supporting neoadjuvant therapy in an off-protocol manner, participation in clinical trials is recommended for patients with clinical stage III melanoma when possible.

2. What is needed to change surgical clinical practice? Current evidence suggests that further refinement of criteria for selecting patients for limited surgical resection for potentially surgically curable disease is needed before this approach can be adopted safely as the standard of care. A phase III randomized controlled trial comparing TLND with more limited lymph node surgery for patients with high-risk stage III melanoma who have a MPR to neoadjuvant therapy, perhaps also guided by blood or tissue biomarkers, would be ideal. Feasibility of this approach also requires scalable adoption of the INMC pathology assessment of immunotherapy-treated lymph nodes to categorize pathologic response and agreement from pathologists. In view of the substantially lower (21%) pCR rate in SWOG 1801

[a]Toxicity only reported by the number of events.

compared with the pCR rate following neoadjuvant doublets (57%) in the OpACIN-neo (most active arm) and relatlimab-nivolumab studies (both with even higher rates of MPR of 63%-64%), another important consideration is whether the optimal neoadjuvant approach should focus on achieving high pCR rates to drive de-escalation of operation (and adjuvant therapies). More mature RFS data from existing studies may help address this question and provide future guidance. Technical considerations also need to be addressed, including best practices to broadly improve short- and long-term surgical outcomes as well as continued structured assessment of the effect of various neoadjuvant regimens on the conduct of the operation. Extensive fibrosis from a robust response to treatment may hinder even limited surgical resection and confound intraoperative assessment of the extent of disease. As we await further advances in the field, data from ongoing trials, and exploration of new strategies for accurate assessment of extent of disease following neoadjuvant immunotherapy, the gold standard operation for clinically evident stage III melanoma remains TLND.

3. Is adjuvant therapy required after neoadjuvant treatment?

In addition to the neoadjuvant phase, most trials have included an adjuvant phase to complete a total of one year of systemic therapy, analogous to current adjuvant therapy regimens. Currently, there is no clear consensus regarding whether the adjuvant phase of therapy is essential or can be omitted and there is no clarity on which patients are ideal for omission of therapy. The use of adjuvant therapy also effects RFS data and can make data harder to interpret. In an attempt to lessen planned surgical and adjuvant therapy approach, the PRADO trial omitted TLND and adjuvant medical therapy in patients achieving MPR. Patients with pathologic partial response underwent TLND only, whereas patients with pNR underwent TLND and adjuvant systemic therapy with or without synchronous adjuvant radiotherapy. In this trial, Blank et al showed that TLND and all adjuvant therapies were omitted in 59 of 60 patients with major pathologic response, and the 24-month relapse-free survival and distant metastasis-free survival rates were 93% and 98% in patients with MPR, 64% and 64% in patients with pPR, and 71% and 76% in patients with pNR, respectively.[11] In patients with pPR having surprisingly poorer outcomes than patients with pNR, the omission of the adjuvant medical therapy does not appear to be optimal for this patient population. This trial opens a new future perspective where the extent of pathologic response from neoadjuvant therapy may direct the decision of whether incorporation of an adjuvant phase is needed,[14] as is being evaluated in the NADINA trial (ClinicalTrials.gov identifier: NCT04949113).

While this approach needs further investigation, to develop a standard and permit cross-trial comparisons, the INMC recommends that neoadjuvant clinical trials include a conventional postoperative adjuvant phase, which may or may not include the drug(s) under investigation, to complete a total duration of 1 year of systemic therapy.[43] Better understanding of the role of adjuvant phase in neoadjuvant immunotherapy remains an ongoing area of research interest to be further investigated in future studies.

CONCLUSION

Patients with clinical stage III melanoma represent a group at high risk for disease recurrence after up-front surgery and adjuvant systemic therapy. Through the work of the INMC, standard guidelines for trial design, patient selection, study end points, and pathologic response criteria have been implemented. Both preclinical and clinical trials have demonstrated improved EFS/RFS outcomes for patients treated in the neoadjuvant setting versus the adjuvant setting. Additionally, patients with any pathologic response to neoadjuvant immunotherapy have durable responses, including improved RFS. There are a number of ongoing and planned trials (Table 1) to explore the efficacy of novel agents or combinations with the goals of improving clinical outcomes, lowering toxicity, and evaluating new drug assets. While there are a number of ongoing questions regarding the neoadjuvant approach, the data thus far support the paradigm shift of considering neoadjuvant therapy for patients with clinical stage III melanoma.

Evolving Management of Stage IV Melanoma

Benjamin Switzer, DO[1]; Sophie Piperno-Neumann, MD, PhD[2]; James Lyon, BS[3]; Elizabeth Buchbinder, MD[3]; and Igor Puzanov, MD, MSCI, FACP[1]

overview

Significant advancements have been made in the treatment of advanced melanoma with the use of immune checkpoint inhibitors, novel immunotherapies, and BRAF/MEK-targeted therapies with numerous frontline treatment options. However, there remains suboptimal evidence to guide treatment decisions in many patients. These include patients with newly diagnosed disease, immune checkpoint inhibitor (ICI)–resistant/ICI-refractory disease, CNS metastases, history of autoimmune disease, and/or immune-related adverse events (irAEs). Uveal melanoma (UM) is a rare melanoma associated with a poor prognosis in the metastatic setting. Systemic treatments, including checkpoint inhibitors, failed to demonstrate any survival benefit. Tebentafusp, a bispecific molecule, is the first treatment to improve overall survival (OS) in patients with HLA A*02:01–positive metastatic UM.

EVOLVING MANAGEMENT OF STAGE IV AND UNRESECTABLE MELANOMA

Elizabeth Buchbinder and James Lyon

Department of Medical Oncology, Dana-Farber Cancer Institute, Boston, MA

ICIs and targeted therapy have improved survival for patients with newly diagnosed metastatic melanoma. Recently, a new ICI combination, nivolumab (nivo) and relatlimab (rela), was approved for patients with metastatic melanoma after demonstrating efficacy in untreated patients. The numerous treatment options available for patients with metastatic disease have complicated the decisions faced by physicians and patients. In addition, more and more patients are receiving therapy earlier in the course of their disease, in the neoadjuvant or adjuvant setting, so that they have potentially resistant disease when metastasis is found.

Early studies on the use of ICIs in the treatment of metastatic melanoma showed significant improvements in progression-free survival (PFS) and OS over previously available therapies. PD-1 inhibitors, such as pembrolizumab (pembro) and nivo,[1,2] and cytotoxic T-lymphocyte antigen 4 (CTLA-4) inhibitors, such as ipilimumab (ipi), function by preventing inactivation of T-lymphocyte activity by cancer cells, leading to improved immune system activation and targeting of neoplastic cells. Ipi was the first agent to be associated with an improvement in survival in metastatic melanoma with a response rate of 11% (95% CI, 6.3 to 17.4). Nivo and pembro were demonstrated to have even greater benefit with response rates in the 30%-40% range, and the greatest initial response rate of 58% (95% CI, 45.9 to 68.5) is observed when PD-1 inhibition is combined with CTLA-4 inhibition.[3,4] These results were found to be consistent across different patient cohorts, but some factors including tumor PD-L1 status and *BRAF* mutation status have trends that are sometimes used to help make initial treatment selection.[3,4]

Recent development of the LAG-3 inhibitor, rela, expanded options for the treatment of metastatic melanoma. LAG-3 is a cell surface molecule that functions as a negative regulator of T-cell proliferation and function, and rela is a first-in-class lymphocyte activation gene 3 protein (LAG-3) blocking antibody that prevents T-cell inactivation by tumor cells. The 2022 study RELATIVITY-047 showed that combination of rela/nivo had twice the median PFS and a 25% reduction in risk of disease progression (PD) or death compared with nivo alone (hazard ratio [HR], 0.75; P = .006). The benefits observed with nivo/rela were similar to the benefits observed in combination PD-1/CTLA-4 therapy although the response rates on both arms were lower at 43% and 32%, respectively.[5]

The selection of frontline therapy for patients with metastatic disease is often based on patient characteristics and preferences. As a result, the autoimmune toxicities associated with different regimens play a huge role. While the rate of grade III/IV treatment-related AEs associated with single-agent PD-1 inhibition is roughly 10%-14%, the rate of grade III/IV treatment-related AEs associated with combination of ipi/nivo is roughly 55% and must be considered when selecting patients to receive this regimen. The rate of grade III-IV AEs observed with nivo/rela is somewhere between single-agent PD-1 inhibition and combination therapy at 18.9%.

Modifications in the dosing of combination of ipi/nivo regimens have shown some effectiveness in reducing the incidence of high-grade AEs associated with ICI

PRACTICAL APPLICATIONS

Participants should be able to

- discuss selection of frontline therapy for metastatic melanoma,
- understand the choices for patients progressing after frontline therapy,
- select proper therapy for patients with melanoma brain metastases,
- understand the unique nature of uveal melanoma and its therapy, and
- support the enrollment on well-designed clinical trials to improve future therapy for metastatic melanoma.

treatment. The CheckMate 511 study found that using flipped-dose ipi/nivo (nivo 3 mg/kg plus ipi 1 mg/kg every 3 weeks for four doses followed by nivo maintenance) lowered the incidence of grade III-V AEs by 14% ($P = .006$) with overlapping OS and PFS curves.[6] However, the data with this regimen are much less mature than those with regular dose ipi/nivo, leading some clinicians to be concerned that responses might not be as durable.

Approximately 40%-50% of melanomas are found to have a mutation in the *BRAF* gene at the V600 location, and there have been numerous studies focused on the use of targeted BRAF and MEK inhibition in treatment of melanomas.[7-10] *BRAF* and *MEK* are both genes functioning in the mitogen-activated protein kinase (MAPK) signal transduction pathway, leading to increased cell division and proliferation, and, when mutated, become overactive with resultant tumor growth. The *BRAF* inhibitors vemurafenib (vem) and dabrafenib (dab) have efficacy as monotherapies in metastatic melanoma with *BRAF* V600E or V600K mutations. However, acquired resistance to *BRAF* inhibitors often develops due to aberrant reactivation of the MAPK pathway. Studies have shown that combining dab with the *MEK* inhibitor trametinib (tram) leads to improvements in treatment response in this population of patients, when compared with dab alone, because of delayed emergence of resistance.[7] These benefits have been observed even in long-term treatment, as evidenced in a 5-year landmark analysis showing long-term survival, particularly in patients with favorable baseline prognostic features.[8] Other combinations of BRAF/MEK inhibitors have also demonstrated benefit in the treatment of melanoma, which include vemurafenib with cobimetinib and encorafenib with binimetinib.[9,10] However, the combination of *BRAF/MEK* regimens is not without side effects and treatment with them carries a rate of grade III-IV AEs of 55% although side effects often respond quickly to treatment holds or reduction.

The question of which therapy, ICIs or targeted therapy, to start in patients with advanced *BRAF* V600 E/K–mutant melanoma was recently answered by two trials: the DREAMSeq and SECOMBIT trials. The DREAMSeq trial investigated optimal sequencing of treatment for patients with *BRAF* V600E/K–mutant melanoma by comparing ipi/nivo followed by dab/tram at progression against dab/tram followed by ipi/nivo at progression.[11] The study found that starting with ipi/nivo was associated with higher 2-year OS and durability of disease response versus the inverse sequence of dab/tram followed by ipi/nivo in all clinical subgroups examined. Recent tumor biology studies have suggested that resistance to *BRAF/MEK* inhibitor therapy results in a locally immunosuppressive tumor environment, preventing effective antigen presentation and immune system activation, and that initial treatment with immunotherapy may actually enhance responsiveness to targeted therapies among *BRAF*-mutated cancers. This study concluded that among patients with metastatic melanoma and *BRAF* V600E/K–mutated tumors, ipi/nivo should be considered the preferred first-line therapy for the majority of patients and has cemented ICI as the first-line choice for all patients with melanoma regardless of mutation status.[11] The SECOMBIT study was a phase II trial that randomly assigned patients to a combination of ipi/nivo, enco/bini, or enco/bini for 8 weeks, followed by ipi/nivo. It found a 3-year OS of 54% (95% CI, 41 to 67) for enco/bini as initial therapy, 62% (95% CI, 48 to 76) for ipi/nivo as initial therapy, and 60% (95% CI, 58 to 72) for a short course of targeted therapy followed by immunotherapy.[12] This trial confirms the benefit of starting patients with *BRAF* V600 mutations on immunotherapy. It also provides an alternate approach to be used in patients started on targeted therapy who did well with a switch at 8 weeks to immunotherapy.

Trials have been performed looking at the combination of ICI with *BRAF/MEK* inhibition. One such study, evaluating the efficacy of triplet therapy with dabrafenib/trametinib/pembro, found that this regimen conferred longer PFS and durability of response, although with greater toxicity than dabrafenib/trametinib alone (with a grade III-V AE rate of 58%).[13] Another trial examined vemurafenib, cobimetinib, and atezolizumab in combination and demonstrated a PFS benefit over targeted therapy alone.[14] However, the clinical application of triplet therapies has been limited by high toxicity rates and lack of comparison with ipi/nivo, nivo/rela, or single-agent ICI treatment. Further studies are ongoing on how best to combine immunotherapy with *BRAF/MEK*-targeted therapy.

The question that clinicians are faced with when discussing immune checkpoint inhibition with patients who have newly diagnosed metastatic melanoma is which ICI regimen to start. The options include single-agent PD-1 inhibition, combination of ipi/nivo at normal dosing or flipped dosing, and combination of nivo/rela. Each of these regimens have different levels of efficacy and different rates of severe

autoimmune toxicities. Factors that are used to make the decision include *BRAF* mutation, location of metastasis, symptoms associated with melanoma, and the underlying fitness and comorbid medical issues of patients. In addition, many patients have received ICI in the neoadjuvant or adjuvant setting before being diagnosed with metastatic disease, and this influences treatment choice (Table 1).

As noted earlier, many patients with metastatic melanoma are diagnosed after treatment with neoadjuvant or adjuvant PD-1 inhibition and thus have disease resistant to PD-1 inhibitor therapy. In patients previously treated with PD-1 inhibition alone, studies have demonstrated that the combination of immunotherapy with ipilimumab and nivolumab is more effective than ipilimumab alone with a rough response rate of 30% (95% CI, 18.4 to 40.6).[15,16] Data for nivolumab and relatlimab in patients who progressed on previous PD-1 inhibition are poor with a response rate of 12% (95% CI, 8.8 to 15.8).[17] Thus, in patients who progressed on adjuvant therapy, the combination of ipi/nivo would be predicted to have the highest response rate.

Trials testing novel agents in combination with PD-1 inhibition in initial treatment of patients with metastatic melanoma have had mixed success. Although Lag-3 inhibition was successful, three recent trials aimed at increasing tumor immune infiltrate all failed to improve treatment over PD-1 inhibition alone. These include an IDO inhibitor (epacadostat), a modified injectable herpes virus (talimogene laherparepvec), and a modified interleukin-2 (IL-2) agonist (bempegaldesleukin). Current frontline clinical trials are testing PD-1 inhibition in combination with HDAC inhibition, novel immunotherapies, vaccines, and many other agents. There are also efforts to test the administration of tumor-infiltrating lymphocytes (TILs) in treatment-naïve patients. TIL therapy involves extraction of infiltrating lymphocytes within tumors, ex vivo outgrowth and expansion of these cells, and adoptive transfer of the cells back to the patient with preparative lymphodepleting chemotherapy and IL-2. Objective responses have been observed among approximately one third of patients, and even in patients with heavily pretreated disease, and it was shown to be superior to single-agent ipilimumab in PD-1–refractory patients.[18-20]

Given the severe immune toxicities associated with ICIs, there are several important frontline trials looking at adding drugs to the combination of ipilimumab and nivolumab to reduce side effects. The addition of granulocyte-macrophage colony-stimulating factor to ipilimumab was previously shown to decrease toxicity, and a current study is testing this with the combination of ipi/nivo.[21] Ongoing studies are showing some promise in the use of tocilizumab, an IL-6 inhibitor, to reduce immune-related adverse effects, after finding increased expression of IL-6 in tumor tissue from patients treated with immune checkpoint inhibitors (ClinicalTrials.gov identifier: NCT03999749).

CHALLENGING SCENARIOS IN STAGE IV MELANOMA

PD-1–Refractory Melanoma: Current Approaches and Future Considerations

Anti–PD-1 ICIs, both as a monotherapy and as a combination with either anti-CTLA4 or anti-LAG3 agents, provide robust and durable response rates in a large percentage of patients with advanced melanoma and are now a widely accepted backbone of frontline treatment, regardless of *BRAFV600* mutational status.[5,22-24] However, a large percentage of patients exhibit either primary resistance or acquired resistance after anti–PD-1 therapy.[25] The management of these patients presents an unmet need.[25,26]

Although continuous enrollment on prospective clinical trials remains the encouraged approach, we already have important insights available. The phase II SWOG S1616 trial focused on patients who exhibited a complete lack of response to anti–PD-1 (or PD-L1) monotherapy by treating them with ipi alone or in combination with continuous nivo. A significant PFS benefit was observed with the combination of ipi/nivo compared with ipi monotherapy (HR, 0.63; 90% CI, 0.41 to 0.97; $P = .037$) with the 6-month PFS of 34% and 13%, respectively.[27] This study also noted intriguing enhancement of intratumoral CD8+ cells in the tumor microenvironment (TME) with the combination of ICIs, particularly among those with a response, suggesting that anti-CTLA4 ICI may reverse primary resistance to the PD-1/L1 blockade. An additional prospective effort combining low-dose ipi (1 mg/kg every 3 weeks for four doses) with pembro in patients who progressed on anti–PD-1/L1 monotherapy noted a median PFS and OS of 5 and 24.7 months, respectively, and a duration of response of 16.6 months (95% CI, 7.9 to not reached).[16] These observations support consideration of combination of ipi plus anti–PD-1 in patients exhibiting resistance to frontline anti–PD-1 monotherapy. A reasonable alternative currently used for patients exhibiting primary or secondary resistance to anti–PD-1 ICI (without CNS involvement) includes the combination of nivo/rela. This is based on a promising signal of enhanced objective response rates (ORRs) and disease control rates of 12% and 45%, respectively, in a phase I/II patient cohort with advanced melanoma that progressed on or after previous anti–PD-1.[5,28] However, these data remain relatively immature awaiting long-term follow-up.

Targeted *BRAF* plus *MEK* inhibition is an approved therapy for patients with anti–PD-1-refractory *BRAFV6000*-mutant melanoma. *BRAF/MEK* inhibitors are commonly used in

TABLE 1. Treatments for Metastatic Melanoma

Line of Therapy	Patient Characteristics		First Choice of Regimen	Alternate Option	
First line	*BRAF*-mutant, reasonable PS	Brain metastasis, symptomatic metastasis, high M stage, high LDH	Ipilimumab and nivolumab	Nivolumab and relatlimab	Clinical trial first choice whenever available!!
	BRAF wt, reasonable PS	No brain metastasis, lower M stage	Nivolumab and relatlimab	Ipilimumab and nivolumab	
	Poor PS, autoimmune disorders	No brain metastasis	Single-agent PD-1 inhibition	BRAF/MEK inhibition if *BRAF V600*–positive	
	Progression on adjuvant PD-1 therapy		Ipilimumab and nivolumab	Nivolumab and relatlimab[a]	
Second line	Previous ipilimumab and nivolumab		BRAF/MEK inhibition if *BRAF V600*–positive	Nivolumab and relatlimab[a]	
	Previous PD-1 alone or nivolumab and relatlimab	Reasonable PS for additional therapy	Ipilimumab and nivolumab	BRAF/MEK inhibition if *BRAF V600*–positive	

Abbreviations: LDH, lactate dehydrogenase; M, metastasis; PS, performance status; wt, wild-type.
[a]Response rate for nivolumab/relatlimab post–PD-1 inhibition is 12%, which must be discussed when considering this regimen.

patients (1) who are considered ineligible for further ICI agents, (2) who require rapid disease control, and/or (3) who progress on combination of ICIs. The latter scenario is founded on early signals, suggesting CTLA-4 resistance in those previously receiving anti-PD1 plus anti-LAG3 regimens, with further validation needed.[29] Additional support for subsequent *BRAF/MEK* inhibition includes a post hoc analysis of the phase III (KEYNOTE-006) trial, where subsequent *BRAF/MEK* inhibition in patients with advanced melanoma who progressed on pembro achieved an ORR of 30.5% (95% CI, 19.2 to 43.9).[30] Given the suboptimal outcomes of targeted agents when compared with ICI regimens in the frontline setting, alternative options are needed in the anti-PD1 refractory setting.[31,32]

The underlying biology responsible for ICI resistance in melanoma is complex and remains a field of active investigation.[25,33,34] The TME appears to play a crucial role in the immunologic suppression by (1) lack of T-cell priming, (2) immune tolerance, (3) stromal adaptations, and (4) enhanced exhaustion of antitumoral CD8+ T cells with concurrent upregulation of regulatory T cells.[33] Given the high mutational burden associated with melanoma, the utilization of advanced single-cell spatial profiling of non–T-cell-inflamed and low interferon-γ expressing (cold) tumors is anticipated to provide neoepitope targets to be recognized by T lymphocytes and provides the basis of peptide vaccine therapies.[35] This approach has recently led to US Food and Drug Administration (FDA) fast-track approval of a personalized neoepitope vaccine (EVX-01) combined with anti–PD-1 (pembrolizumab) in the phase II study (KEYNOTE-D36).[36] Finally, although not FDA-approved at the time of this publication, an exciting non-ICI treatment option for patients with anti–PD-1 refractory melanoma includes adoptive cell therapy with TILs. A phase II trial with an autologous, centrally manufactured TIL (lifileucel) has observed an ORR of 36% (95% CI, 25 to 49), with 41.7% of these lasting for more than 24 moths and a median OS of 17.4 months, in a heavily pretreated patient cohort with PD-1–refractory melanoma.[19] A randomized phase III (M14TIL) trial comparing TIL therapy with ipilimumab monotherapy noted an ORR of 49% (95% CI, 38 to 60) vs 21% (95% CI, 13 to 32) along with a median PFS of 7.2 vs 3.1 months, respectively, in a cohort of patients with mostly PD-1 monotherapy–refractory melanoma.[20] Finally, a plethora of alternative approaches for patients with PD-1–refractory melanoma are ongoing.[23,37]

CNS Involvement

Metastatic disease involving CNS portends a poor prognosis. Melanoma brain metastases (MBM) occur at high rate (40%-60%) and account for approximately 54% of melanoma deaths.[38] This high-risk subset remains underrepresented in trials given exclusion of MBM in major clinical trials to date. However, retrospective and small prospective studies dedicated to this group revealed important observations leading to substantial improvements in response and survival for certain subsets of patients.[38-40]

The phase II COMBI-MB trial, with *BRAF/MEK* combination (dabrafenib plus trametinib) in patients with *BRAFV600* mutation, achieved intracranial responses in 58% (95% CI, 46 to 69) of patients with asymptomatic and treatment-naïve disease, a median duration of response of 6.5 (95% CI, 4.9 to 10.3) months, a mPFS of 5.6 (95% CI, 5.3 to 7.4) months, and an OS of 10.8 (95% CI, 8.7 to 19.6) months.[41] Additional studies involving *BRAF* and *MEK* inhibitors at higher doses (ClinicalTrials.gov identifier: NCT03911869) or in combination with ICIs (ClinicalTrials.gov identifiers: NCT03625141 and NCT04511013) and novel agents

(ClinicalTrials.gov identifier: NCT02159066) for patients with *BRAFV600*-mutant MBM are ongoing.[38]

In patients with asymptomatic MBM, a phase II trial with anti-CTLA4 (ipilimumab) achieved intracranial disease control at 12 weeks in 24% with a median OS of 7 months (95% CI, 4.1 to 10.8).[42] A phase II trial with anti-PD1 (pembrolizumab) noted an ORR of 22% and a median OS of 17 months (95% CI, 10 to not reached) in a similar population.[43] Similar response rates (20%; 95% CI, 7 to 41) were observed in the phase II (ABC) trial using anti–PD-1 (nivolumab) for patients with asymptomatic MBM.[44] Five-year intracranial PFS and OS rates of 46% and 51% for the ipi/nivo ABC trial arm, compared with 15% and 34% for nivolumab monotherapy in the asymptomatic patient cohort, were observed. The combination of ipilimumab plus nivolumab phase II (CheckMate 204) trial observed an ORR of 54% (95% CI, 43.3 to 63.5) and a 36-month intracranial PFS of 54% (OS 72%) for patients with asymptomatic MBM.[45,46] Given the durable intra- and extracranial response and survival rates observed in these two trials, up-front combination of ICIs (ipilimumab plus nivolumab) is currently considered an optimal approach for patients with asymptomatic MBM. This combination is preferred over frontline targeted therapy in patients with asymptomatic MBM and *BRAFV600* mutation, supported by expert consensus and prospective and real-world analyses.[31,32,47,48] Prospective trials are ongoing to elucidate the additional benefit of ICI combined with stereotactic radiosurgery (SRS) or *BRAF/MEK* (ClinicalTrials.gov identifier: NCT04511013).[40,49-53]

Patients with symptomatic MBM, requiring >10 mg daily prednisone-equivalent steroids, exhibited substantially worse response and survival rates in all trials where such cohorts were included.[40,46] These likely reflect a larger disease burden, need for larger doses of systemic steroids, and unique TME.[38] Responses to ICI are reduced in those with exclusively intracranial disease, suggesting that ICI may augment CD8+ T-cell trafficking via peripheral immune T-cell expansion to achieve a more robust intracranial response.[40,54] Development of relevant biomarkers is an area of ongoing research.[26,55]

Additional Considerations: Autoimmune Disease

Given the systemic autoinflammatory pathophysiology associated with irAEs, patients with an underlying autoimmune disease have historically been excluded from major clinical trials and therefore are largely under-represented within the currently available prospective data, supporting ICIs in a variety of cancer subtypes.[56] A systematic review of patients with cancer (mostly melanoma) and concurrent autoimmune disease noted 41% experienced a flare of their underlying condition, 25% developed de novo irAEs, and 9% experienced both preexisting flares and de novo events upon initiation of ICI, with a signal of anti-CTLA4 ICI more commonly associated with flares of the underlying disease and anti-PD1 ICI triggering new irAEs.[56] Importantly, there was no observed difference in irAE rates in those with active compared with inactive pre-existing autoimmunity at the time of ICI initiation, and although irAEs were controlled without the need to discontinue ICI in more than half of the patients, the rates of grade 5 irAEs were higher than the general population at 2.4%.[56] Additional cohort studies observed that 71% of patients with underlying autoimmune diseases developed either worsening of their pre-existing condition or a new irAE on initiation of ICI.[57] This study also noted a trend in reduced PFS in those with autoimmune flares and irAEs compared with those without such events, mostly in patients requiring systemic immunosuppressants and/or ICI discontinuation.[57] The high doses of systemic glucocorticoids, especially in the early phases of ICI initiation, may blunt the response to ICI that is historically associated with patients who develop irAE compared with those who do not.[58-60] These observations suggest that the use of systemic glucocorticoids, although oftentimes required in the management of severe irAE, should be considered judiciously in those experiencing low-grade irAE events and/or indolent autoimmune conditions especially in the early phases of ICI initiation.[58,61-64]

UVEAL MELANOMA: CHANGING PARADIGMS OF TREATMENT

Sophie Piperno-Neumann

Department of Medical Oncology, Institute Curie, Paris, France

UM is the most common primary intraocular malignancy in adults, albeit a rare melanoma subtype, characterized by the absence of *BRAF*, *NRAS*, or *KIT* mutation but recurrent, mutually exclusive, and early oncogenic mutations in the Gαq pathway (mostly *GNAQ/11*)[65]; the inactivation of these Gα proteins results in activation of downstream signaling cascades, including the MAPK, PI3K-AKT, and YAP pathways.[66]

Despite a highly effective management of the ocular tumor, up to 50% of patients develop metastases by hematogenous dissemination, with occult micrometastases before the detection of the primary eye tumor. The liver is the first site of metastasis in more than 90% of patients.[67] Because of limited efficacy of available regional and systemic therapies, OS is poor and the historical median OS is 1 year after the first metastatic event.[68,69] Until recently, no systemic treatment had demonstrated any survival benefit. In January 2022, tebentafusp became the first systemic therapy to receive regulatory approval in this treatment-resistant cancer.

Tebentafusp is a T-cell–redirecting bispecific fusion protein HLA A*02:01–restricted, using a high-affinity T-cell receptor targeting glycoprotein 100 (gp100), a melanocyte

lineage–specific antigen highly expressed on UM cells, and fused to an anti-CD3 single-chain variable fragment. Once bound to the gp100-HLA complex, tebentafusp recruits and activates polyclonal T cells through CD3 ligation to release cytokines and cytolytic mediators.[70]

In the open-label, phase III, IMCgp100-202 trial, 378 HLA A*02:01–positive patients with first-line systemic metastatic UM were randomly assigned (2:1) to receive tebentafusp or the investigator's choice of pembrolizumab (82%), ipilimumab, or dacarbazine. After a median follow-up of 14 months, the improvement in OS was highly significant, with an estimated median OS duration of 21.7 months in the tebentafusp group versus 16 months in the control group and a 1-year OS rate of 73% versus 59% (HR, 0.51; 95% CI, 0.37 to 0.71; $P < .001$).[71] This unprecedented result is weighted by a modest although significant benefit in PFS (median PFS 3.3 *v* 2.9 months; 31% *v* 19% at 6 months; HR, 0.73, 95% CI, 0.58 to 0.94; $P = .01$) and a low ORR of 9% versus 5%.

Moreover, an OS benefit was observed in patients with best objective response of RECIST 1.1 PD on tebentafusp compared with the control group (HR, 0.43) and who continued tebentafusp beyond initial radiographic progression. According to the protocol, 109 patients received tebentafusp beyond progression and 39 had a clinical benefit (ORR or SD >3 months); the OS benefit was sustainable after adjusting for all covariates (HR, 0.7).[72] Investigations are underway to understand the decoupling of RECIST-based radiographic assessment and OS benefit: There is a need for new measures of clinical activity with this new class of immuno-oncology therapies and for predictive biomarkers of response or resistance.

Indeed, the underlying practical question is closely related to the optimal way to monitor tebentafusp treatment: (1) in patients with stable disease for uninterrupted months or years of weekly infusions and (2) in patients with RECIST or irRECIST PD in the absence of any disease symptoms or treatment-related AEs. What is the optimal duration of treatment? Which discontinuation rules can be outlined?

Because of the lack of correlation between survival benefit and OR rate and a weak PFS gain in tebentafusp versus the investigator's choice, an update of the 202 trial with longer follow-up is very much awaited.

UM has a very low mutational burden, making analysis of circulating tumor DNA (ctDNA) challenging.[73] In a single-arm, phase II trial of tebentafusp in 127 previously treated patients with metastatic UM, 84% with evaluable serum samples had detectable ctDNA at baseline and on treatment, measured with multiplex PCR followed by next-generation sequencing for major UM-specific genes (*GNAQ*, *GNA11*, *SF3B1*, *PLCB4*, *CYSLTR2*, *EIF1AX*). The magnitude of ctDNA reduction after 9 weeks of tebentafusp correlated with improvement in OS using a logarithmic scale ($R^2 = 0.88$, $P < .0001$): 14% of patients achieved complete ctDNA clearance, including patients with a best response of PD.[74] TILs and tumor necrosis may mimic a radiographic progression with changes in tumor size because of immune infiltration and activation rather than tumor growth; further studies are needed to confirm that ctDNA is a surrogate marker more accurate than imaging response criteria to assess tebentafusp benefit in patients with metastatic UM. ctDNA results from the prospective phase III trial 202 are required before ctDNA analyses can be added to routine clinical practice to early identify patients benefiting most from tebentafusp.

Assessment of OR by RECIST or irRECIST criteria underestimates the clinical benefit from tebentafusp treatment. Considering growth kinetics and providing a quantitative evaluation of tumor volume changes over time on the basis of the sum of the largest target lesion diameters, the tumor growth rate may provide additional information compared with standard RECIST criteria on the basis of unidimensional assessment of target lesions.[75]

Moreover, the mechanism of action and the safety profile of tebentafusp may encourage trials combining or sequencing tebentafusp with other systemic treatments. Preclinical data suggest that tebentafusp induces and potentiates antigen cross-presentation by dendritic cells.[76] The changes induced by tebentafusp in the tumor TME may increase the efficacy of the checkpoint blockade; this is attested by post-tebentafusp biopsies showing increased expression of PD-L1 and PD-1. To investigate the outcomes from patients treated with checkpoint inhibition (CPI), pre- or post-tebentafusp may help to build the next prospective clinical trials in UM.

Regional therapies could also be tested with tebentafusp in selected patients with UM with a limited metastatic disease, combining clinical outcomes and immunologic end points.

Finally, adjuvant and/or neoadjuvant studies should be launched in the near future for patients at high risk of metastasis through international collaborations and networks including the Collaborative Ocular Oncology Group, the International Rare Cancer Initiative, EURACAN, and Patient Advocacy Groups as Cure OM and Melanoma Patient Network Europe.[77]

IMC-F106C, a new bispecific molecule targeting an HLA A*02:01–restricted epitope of PRAME, the most broadly expressed cancer testis antigen in many tumors, such as lung, ovarian, endometrial, or melanoma, is currently tested as a single agent and in combination with CPI (ClinicalTrials.gov identifier: NCT04262466). Preliminary results showed durable RECIST partial responses and ctDNA response in PRAME-positive patients across multiple tumor types, including UM.[78]

A major limitation of immune-mobilizing monoclonal T-cell receptor against cancer (ImmTAC) molecules is HLA restriction. Main ImmTACs target HLA A*02, which is represented at its highest frequency (around 45%) in the White population.[79] For patients with metastatic UM who are not HLA A*02:01–positive, current options are locoregional strategies focused on the liver, alone or combined with systemic therapies, depending on the extent of metastases; CPI in monotherapy or combination with no evidence of survival benefit; or a clinical trial.[66]

One alternative for half of patients with HLA A*02:01–negative UM could be the development of ImmTACs targeting peptides on other HLA alleles. Other challenges for T-cell–engaging bispecific molecules include selecting the most relevant targets, achieving optimal dosing, reaching higher efficacy, and overcoming tumor resistance.[80]

Giving the immunosuppressive hepatic microenvironment in UM metastases, exploration of new immunotherapy strategies to enhance antitumor immune response is of high interest. Cellular therapies with autologous TILs harvested from UM metastases demonstrated an ORR of 35% in 20 evaluable patients in a single-center phase II study, but survival data are lacking.[81]

LAG-3 is a negative regulator of T cells, leading to immune escape of cancers through T-cell dysfunction and immune exhaustion.[82] Single-cell RNA sequencing showed that most CD8 cytotoxic T cells in UM expressed LAG3 at a high level and correlated with high risk of metastasis.[83,84] A single-arm, Simon, two-stage, phase II trial of relatlimab and nivolumab in patients with metastatic UM is recruiting (ClinicalTrials.gov identifier: NCT04552223).

The combination of MDM2 inhibitor APG-115 with pembrolizumab has demonstrated synergy in vitro via depletion of M2 macrophages from the TME as a result of p53 activation and is tested in a phase I/II study in solid tumors (ClinicalTrials.gov identifier: NCT03611868), showing encouraging results in UM.[85] Two phase II studies combining lenvatinib and pembrolizumab in patients with CPI-naïve metastatic UM are also recruiting (ClinicalTrials.gov identifiers: NCT05308901 and NCT05282901).

Multiple other emerging strategies are being investigated, including agents targeting protein kinase C, a downstream element of the Gαq signaling pathway. After disappointing results with first-generation sotrastaurin[86] and limited activity of second-generation LXS196/IDE196 in monotherapy,[87] the combination of IDE196/darovasertib with crizotinib showed a promising ORR of 31% in 35 evaluable patients (ClinicalTrials.gov identifier: NCT03947385).[66]

Focal adhesion kinase inhibitors target YAP oncogenic activation related to *GNAQ/11* mutations and are currently evaluated in monotherapy or in combination with MEK inhibitors (ClinicalTrials.gov identifiers: NCT04109456 and NCT04720417).

DYP-688 is a first-in-class PMEL17 targeting antibody-drug conjugate (ADC), a melanocyte lineage protein highly expressed in cutaneous and UM. On ADC binding to PMEL17 on the target cells, the linker is cleaved to release SDZ475, which inhibits *GNAQ/11* oncogenic signaling, resulting in dose-dependent apoptosis. A multicenter phase I/II trial is recruiting patients with metastatic UM and other *GNAQ/11*-mutant melanoma (ClinicalTrials.gov identifier: NCT05415072). Epigenetic approaches and combination of regional and systemic therapies are also developed.[66]

Finally, patient preferences need to be integrated into clinical trials, with the aim of improving patient satisfaction regarding information and supportive care, through tailored patient-reported outcomes[88] and dedicated studies (ClinicalTrials.gov identifier: NCT04728113).

CONCLUSIONS

The frontline treatment for advanced melanoma has significantly evolved in recent years with considerable improvement in disease response and survival. Currently approved first-line treatment options include PD-1 inhibition on its own, combination of nivo/rela, combination of ipi/nivo, and combination of *BRAF/MEK* inhibitors. Future research into biomarkers for treatment selection and tools such as ctDNA to monitor efficacy of therapy will help guide treatment selection.

Challenges remain for treatment of patients with CKI-refractory disease, progression after CKI combinations, CNS involvement, and both pre-existing and acquired autoimmune conditions where clinical trials should be prioritized. Randomized prospective data now exist for anti-CTLA4 (ipi) combined with anti-PD1 (nivo) and for TILs in patients with melanoma resistant to frontline anti-PD1 monotherapy. Data for other second-line options, including TCR engagers and personalized neoepitope vaccines, are eagerly anticipated. The optimal approach to patients with MBM who do not respond or are unable to receive ipi/nivo combination is unknown. dab/tram combination therapy is effective for patients with *BRAF* V600–mutated tumors, but the long-term durability of responses remains suboptimal. Better therapy strategies are needed for patients with pre-existing autoimmune conditions and those who develop higher-grade irAEs on ICI therapies, aiming to preserve the efficacy without worsening both acute and chronic toxicities.

UM is a distinct disease from its skin counterpart. It has a dismal prognosis and does not respond readily to existing therapies. Recent advances in our understanding of its

genomic and immunologic characteristics, driven by dedicated, international collaborations, have resulted in novel promising treatment strategies. Tebentafusp is the first-ever FDA-approved therapy, specifically in UM, improving OS. For the sake of our patients, we hope for more breakthroughs in the near future.

Patient-Reported Outcomes in Pediatric Patients With Cancer

Bryce B. Reeve, PhD[1]; Katie A. Greenzang, MD, EdM[2,3]; and Lillian Sung, MD, PhD[4]

overview

Patient-reported outcomes (PROs) are reported directly by the patients about their own health. The objective of this article was to provide an overview of PROs in pediatric cancer, to describe how PROs can be incorporated into pediatric cancer clinical trials, and to discuss how PROs can guide symptom management treatment choices in pediatric oncology. Pediatric patient self-report provides a distinct voice in describing their experience compared with family caregiver or clinician report. Thus, every effort should be made to allow children to self-report symptoms, functioning, and other quality-of-life impacts and to use that data to inform treatment decision making. In addition to its incorporation into routine clinical care, it is also important to incorporate PROs into clinical trials to understand the patient experience of treatment toxicities and their impact on quality of life. Key considerations include clearly articulated PRO aims, selection of outcomes, choice of PRO measures, and frequency of PRO assessments. Once PROs are integrated into routine clinical care, it will be important to enable evidence-based symptom management. Strategies should be based on clinical practice guidelines (CPGs). Development and adaptation of care pathways on the basis of CPGs is one approach to standardize evidence-based symptom management at individual institutions. PROs are important to pediatric patients with cancer and their families. Self-report should be emphasized wherever possible. Approaches to enable PRO reporting into routine clinical care and enable preventative and therapeutic actions for symptom management are important. These efforts will optimize quality of life for pediatric patients with cancer.

INTRODUCTION

Pediatric patients with cancer have excellent survival outcomes related to improved treatment strategies including immunotherapy and more precise risk stratification.[1] This accomplishment can be attributed to multicenter clinical trials and evidence-based standardization of cancer treatments. However, such standardization has not been achieved across cancer care settings, including supportive care.[2] Supportive care encompasses all aspects of care apart from that related to the cancer diagnosis and treatment and includes quality of life, organ toxicities, and infectious complications as examples. One aspect that is important to patients, their families, their treating clinicians, and researchers is patient-reported outcomes (PROs).[3]

PROs are reported directly by the patients about their own health and include subjective outcomes, such as physical function, pain, nausea, and fatigue.[4] In pediatric cancer, PROs are important because neither clinicians nor caregivers provide concordant ratings compared with those reported by the patients themselves.[5] However, many gaps remain before PROs can be implemented into routine clinical practice and influence clinical actions to address them. The objective of this review was to provide an overview of PROs in pediatric cancer, to describe how PROs can be incorporated into pediatric cancer clinical trials, and to discuss how PROs can guide treatment choices in pediatric oncology. Figure 1 provides an overview of these issues.

Listen to the Children: Giving Children a Voice in Reporting on Their Health-Related Quality of Life

Health-related quality of life (HRQOL) is a broad multidimensional construct that describes the impact of cancer and its treatments on the lives of children in terms of physical, mental, and social well-being.[6-8] As most of the HRQOL domains are subjective in nature,[9] children self-reporting on their HRQOL (ie, PROs) is essential to minimize child suffering and improve tolerance of treatments. If the treating clinicians are aware of what the child is experiencing, they can implement symptom management strategies to make sure the child can continue cancer treatment or consider treatment modification to a less intensive regimen. As a result, the child will receive the maximum benefit from the anticancer treatments.

In adult cancer settings, it is generally accepted that patients should self-report on their HRQOL impact

PRACTICAL APPLICATIONS

- Patient-reported outcomes (PROs) are reported directly by patients about their own health.
- Pediatric patient self-report provides a distinct voice in describing their experience compared with family caregiver or clinician report, and thus, every effort should be made to allow children to self-report their symptoms, functioning, and other quality-of-life impacts.
- Incorporation of PROs into clinical trials provides critical information about toxicities and the tolerability of treatment; important considerations when evaluating PROs in clinical trials include clearly articulated PRO aims, selection of PROs, choice of PRO measures, and frequency of PRO assessments.
- For routine clinical care, symptom management should be based on clinical practice guidelines; development and adaptation of care pathways is one approach to standardize evidence-based symptom management at individual institutions.

using PRO measures. However, in pediatric settings, there is not the same level of buy-in that the child can provide valid information on their HRQOL despite the existence of well-validated PRO measures, such as the National Institutes of Health's (NIH's) Patient-Reported Outcome Measurement Information System (PROMIS) Pediatric measures,[10,11] the National Cancer Institute's (NCI's) Pediatric PRO version of the Common Terminology Criteria for Adverse Events (PRO-CTCAE),[12,13] and the Symptom Screening in Pediatrics Tool (SSPedi).[14-16] Table 1 shows examples of PRO measures that assess multiple HRQOL dimensions. The lower acceptance of PROs in pediatric settings may be due to a lack of awareness of these PRO tools. However, there is a perception that clinician- and family caregiver-proxy reports are sufficient for understanding the child's experiences. Thus, our focus for this section is to examine the extent to which the child provides a distinct voice in describing their HRQOL impact from cancer and treatment. Multiple studies have examined this issue[22-25]; we will summarize some illustrative studies below.

In one of the largest studies to date, Freyer et al[5] examined the level of concordance among the triad of the children, their family caregivers, and their treating clinicians for reporting symptomatic adverse events (AEs) associated with cancer treatment. The total sample included 438 children with 41% between age 7 and 12 years, 30% between age 13 and 15 years, and 29% between age 16 and 18 years. The sample was diverse in terms of sex, race, and cancer types. Most children (92%) were reporting on symptomatic AEs associated with recently received chemotherapy within the past 1-2 weeks, with the remaining children receiving radiation therapy (6%) or hematopoietic cell transplant (2%). The agreement between children and their family caregivers ranged from good for more observable symptoms such as vomiting (weighted kappa = 0.60) to fair for more

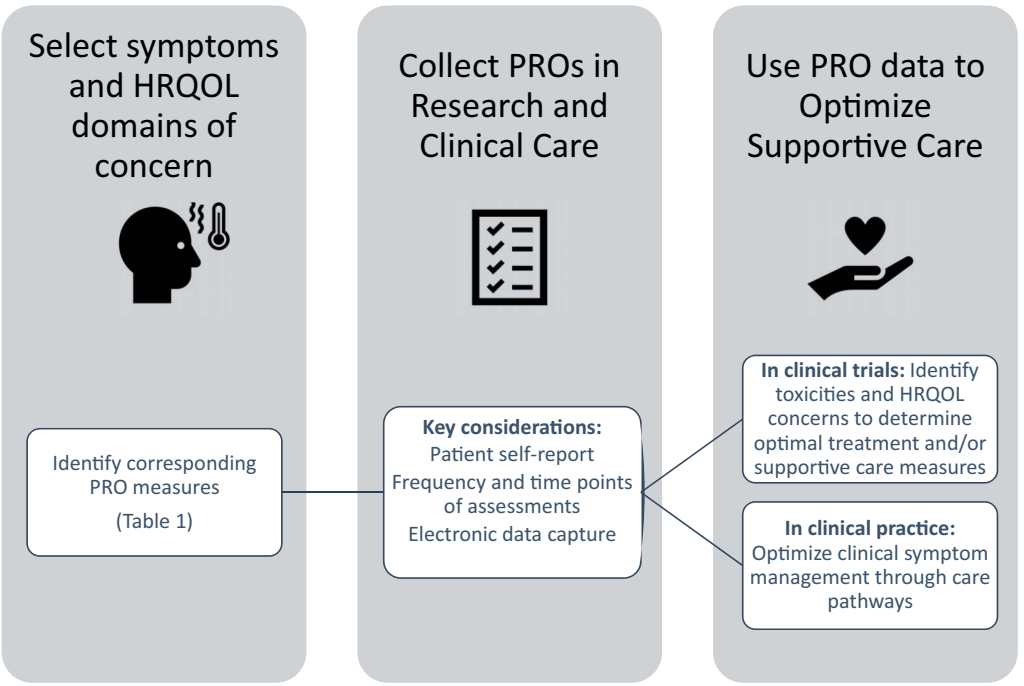

FIG 1. Optimal incorporation of PROs in pediatric oncology research and clinical care. HRQOL, health-related quality of life; PROs, patient-reported outcomes.

TABLE 1. Examples of Patient-Reported Outcome Measures Commonly Used in Pediatric Patients That Capture Multiple Aspects of HRQOL

Patient-Reported Outcome Tool	Age Validated for Self-Report (years)	Constructs Measured
Patient-Reported Outcome Measurement Information System (PROMIS) Pediatric measures[10,11]	8-17	Symptoms, functioning, HRQOL
Pediatric Patient-Reported Outcomes version of the Common Terminology Criteria for Adverse Events (Pediatric PRO-CTCAE)[12,13]	7-18	Symptomatic adverse events
Symptom Screening in Pediatrics Tool (SSPedi)[14-16]	8-18	Bothersome symptoms
Mini-SSPedi[17]	4-7	Bothersome symptoms
Memorial Symptom Assessment Scale[18,19]	7-12; 10-18	Symptoms
Pediatric Quality of Life Inventory (PedsQL)[20]	8-18	HRQOL
KidScreen[21]	8-18	HRQOL

Abbreviation: HRQOL, health-related quality of life.

unobservable symptoms such as depression (weighted kappa = 0.24). The agreement between children and their treating clinicians ranged from fair for more observable symptoms such as anorexia (0.35) to poor for unobservable symptoms such as fatigue (weighted kappa = 0.11) and depression (weighted kappa = 0.15). Across all 15 symptomatic AEs reviewed in the study, consistently clinicians reported significantly lower symptomatic AE grades than children, with family caregivers reporting grades closer but still not similar to the children's self-reports.

Using the same participants from the study of Freyer et al,[5] Maurer et al[26] examined performance status ratings, which are important for determining eligibility for clinical trials. On average, clinicians reported statistically significant better performance status than family caregivers ($P < .01$) using the Lansky Play-Performance Scale (LPPS). Approximately 63% of clinicians placed the child in a higher LPPS level than the caregivers. Using a LPPS threshold of 60 that is commonly used for clinical trial eligibility, 25.6% of clinicians would have deemed a child eligible, but the caregivers reported LPPS scores below the threshold. Moderate correlations were found between the family caregivers' LPPS ratings and the children's self-reported physical function (via PROMIS; $r = 0.45$) and between the clinicians' LPPS ratings and the children's self-reported physical function ($r = 0.35$).

Both the studies summarized above are consistent with other studies and together demonstrate a clear picture that children provide a distinct voice in reporting how cancer and cancer treatment affect their lives physically, mentally, and socially. Every effort should be made to allow children to self-report their HRQOL and to use that data to inform treatment decision making. Most PRO measures are validated for children as young as 8 years as that is a typical age when children can read PRO questions independently.[27] Some PRO measures have been adapted to be completed by children as young as 4-5 years.[15] In a recent survey among 376 pediatric oncology clinicians with at least 2 years of experience treating children with cancer, 99% reported that 6- to 7-year-old children are able to describe their subjective symptoms by 3-4 months postdiagnosis (58% at the time of diagnosis) and 84% of clinicians reported that 4- to 5-year-old children are able to describe their symptoms by 3-4 months postdiagnosis (19% at the time of diagnosis).[28] For 4- to 7-year-old children, almost all clinicians (>97%) reported they would likely use the children's self-reported symptom data for managing the child's symptoms if the data were collected from a validated PRO measure. An advantage of mini-SSPedi (age 4-7 years)[17] and SSPedi (age 8-18 years) is the availability of an audio function that allows the entire instrument or specific questions to be read aloud to the child. As a promising approach to facilitate young children to self-report symptoms, co-SSPedi is a structured dyadic approach in which the child voices symptoms first, and their assessment is supported by their family caregiver.[29,30]

Together, there is strong evidence and support for allowing children to self-report their HRQOL impact and to use that information to inform cancer care. The number of questions that can be included and the frequency of administration are likely to vary by age and acuity of illness such that clinically important PROs can be identified while minimizing patient burden for completing questionnaires. We also want to recognize that both the family caregivers' perspectives and the treating clinicians' perspectives are important in understanding the HRQOL impact on the children. The differences in ratings and scores do not suggest that one reporter is right and the others are wrong. Instead, their reports reflect different experiences and perspectives with the common goal among all to improve the children's HRQOL. Thus, we must learn how to use all three voices to inform care for the children, importantly valuing the children's perspectives that have typically been ignored.[31] There is additional value to learn how to use the family

caregivers' and clinicians' reports, particularly at times when the child is too ill or unable or unwilling to self-report their HRQOL. Recognizing the value of PRO measures for capturing the distinct voices of the children, subsequent sections of this article focus on integrating PROs in clinical trials and how clinicians should respond to PROs whether obtained during routine clinical care or during trials.

Incorporation of PRO Aims and Outcomes in Pediatric Clinical Trials

Rationale for PRO incorporation in pediatric cancer clinical trials. It is not only important to measure PROs during clinical care but also to measure PROs during the conduct of clinical trials. As iterative cooperative group trials have led to tremendous improvements in survival for many pediatric malignancies,[1] many current clinical trials focus on risk-stratified care to reduce treatment toxicities and improve HRQOL for those diseases with excellent outcomes. Other clinical trials seek to improve outcomes for difficult-to-treat diseases through the addition of novel therapeutics, many with poorly described toxicities. Incorporation of PRO aims, measures, and outcomes is critical to understanding the patient experience of these toxicities and the impact of therapy on symptoms and HRQOL during and after treatment. PRO measures can help answer primary study questions about tolerability where there may be similar efficacy between treatment arms, and PROs can help determine what supportive care interventions are needed and when to use them. As described above, it is particularly important that clinical trials incorporate direct patient reporting as clinician and family caregiver reports frequently do not align with the patient experience of toxicities or HRQOL.[5,32] Yet, PRO aims and measures have often been excluded from pediatric clinical trials. Only four of 17 recent drug trials of novel agents in pediatric oncology included PROs,[33] and other studies suggested that PROs are incorporated in <20% of pediatric and adolescent and young adult (AYA) clinical trials.[34,35] In the following sections, we suggest key considerations for optimizing the inclusion of PROs in pediatric cancer clinical trials.

Determination of PRO aims and how they contribute to a study's overarching aims. Early consideration of PROs is important starting from the concept development stage. After identifying key study outcomes and goals, we consider whether some of these outcomes may be best captured by direct patient report or whether a combination of clinical data complimented by PROs may be helpful. For example, in studies that incorporate novel agents in combination with cytotoxic chemotherapy where study outcomes of interest include understanding the added toxicities of novel agents to combination therapy, both clinician-reported and patient-reported toxicities should be used. PRO aims should be structured and written in the same format as disease response and survival aims. They must be clear, specific, and measurable, and their role in determining the primary trial outcome should be clearly apparent. Instead of referring to PROs broadly, we recommend selecting and describing the primary PRO(s) of interest in the aims, even if a more comprehensive battery of PROs will be collected. Moreover, as with any concept to be measured, PROs should only be incorporated in clinical trials if their collection will contribute to a specific study aim.

Optimal measures and outcomes. Similar to the challenges of determining which laboratory studies and biospecimens should be collected in a clinical trial, consideration must be paid to ensuring that all necessary PRO data are collected while minimizing participant burden. The outcomes of interest should be determined before the selection of optimal PRO measures (Table 1). However, it is worth considering the inclusion of some PRO batteries both to allow comparison of PROs across studies over time and to ensure that unexpected toxicities are not overlooked. The NCTN AYA PRO task force recommends inclusion of PROMIS health status short forms to address core HRQOL domains and the PRO-CTCAE and Pediatric PRO-CTCAE to capture symptoms and toxicities, across all AYA clinical trials.[36]

In cross-network clinical trials that enroll both children and adults, there are many existing validated and reliable tools within the public domain that have aligned pediatric and adult measures such as PROMIS.[37] PROMIS measures have well-established psychometric properties in both pediatric and adult oncology populations including responsiveness to change over time.[38-40] The Pediatric and Adult PROMIS measures have been shown to be comparable conceptually across the age continuum with no evidence of differential item functioning on the basis of age.[41] Similarly, PRO-CTCAE and its corresponding pediatric version, the Pediatric PRO-CTCAE, were designed for use in clinical trials to identify patient experience of symptomatic AEs and their change over time. Both the NCI and the Food and Drug Administration have endorsed the use of the Pediatric PRO-CTCAE in pediatric clinical trials.[13,42] These tools can be used to measure patient reports of the frequency, severity, and interference of core symptoms, and additional potential toxicities of interest can also be assessed on the basis of specific treatments. Other study-specific questions can be addressed through the inclusion of other validated measures and items.

Time points of collection. In clinical trials, the frequency and specific time points of PRO collection should be driven by the research question, and decisions need to be made about whether the outcome of interest is the change in PROs over time or the difference between PROs at a given moment in time. For example, in a current cross-network

osteosarcoma trial evaluating the optimal surgical approach to pulmonary metastatic osteosarcoma (COG AOST2031), we are comparing the patient experience of pain between a thoracoscopic approach and open thoracotomy immediately postoperatively and several weeks postoperatively. A study of postoperative pain in adults with lung cancer found that those who underwent a thoracoscopic procedure had significantly less pain immediately postoperatively, but the difference in pain scores between groups decreased over time.[43] Therefore, we were careful to select our time points of interest to ensure that we do not inadvertently miss a clinically important difference in the patient experience by measuring pain at the wrong time.

Ensuring sufficient number of time points and PRO collection beyond active therapy and into survivorship are also important considerations to ensure meaningful data. However, in clinical trials, frequent assessments may prove overly burdensome to respondents and may result in nonparticipation and missing data. Thus, it is important to balance frequent assessments to identify changes in PROs against feasibility and respondent burden. Furthermore, large time lapses between PRO assessments or extending PRO assessments far into the post-treatment period come with concerns of losing patients to follow-up or decreased engagement.[44]

PRO data collection strategies and the role of electronic data collection. Historically, paper-and-pencil data collection has been used in pediatric clinical trials despite the associated inefficiencies of data collection and data entry and despite patient preference for electronic data capture (EDC).[45] PROMIS, PRO-CTCAE, and SSPedi have electronic data collection options that can be completed on a patient's own computer, smartphone, or tablet. EDC also allows for central PRO collection, thereby substantially minimizing individual participating site burden. The NCTN AYA Task Force and the Children's Oncology Group have recently devoted substantial resources and efforts to develop and pilot an EDC strategy using the REDCap platform in several cross-network trials. However, electronic data collection, particularly in pediatric clinical trials, requires further research. Unanswered questions include the optimal strategy for ensuring direct patient report from younger children who may not have their own electronic device. There is also some concern that EDC may not be as successful for some particularly vulnerable populations.[46] Finally, although central EDC relieves some of the site burden in PRO data collection, individual sites may be unaware of concerning symptoms reported by patients using PRO measures. Future PROs collected via EDC in cooperative group clinical trials may consider using existing strategies to report back worrisome patient-reported toxicities to clinicians, particularly those that may require timely intervention such as uncontrolled severe pain.

Who are we missing? Throughout these efforts to incorporate PROs in pediatric cancer clinical trials, we must continually ask ourselves whose voices may be missing. Optimal strategies for including the concerns of very young patients and ways of ensuring participation and representation of vulnerable populations with differential access to, or comfort with, EDC are warranted. Furthermore, although adult PRO measures have available translations in numerous languages, translations of pediatric PRO measures are greatly lacking and limit our knowledge of the experiences of many children. Despite these ongoing questions and challenges, PRO collection in pediatric clinical trials plays an important role in our understanding of toxicities, treatment tolerability, and long-term outcomes of treatments investigated in clinical trials. The following section examines how symptoms identified by PRO measures should be addressed in health care delivery settings.

How PROs Can Guide Symptom Management Treatment Choices in Pediatric Oncology

Approaches to prevent and treat symptoms. Whether PROs are identified during routine clinical care or during conduct of a clinical trial, it is important that clinicians act on these reports. More specifically, action to prevent and treat toxicities and concerns identified through PROs is critical to optimizing supportive care and symptom burden. One of the many challenges to symptom control is the multitude of possible symptoms, with each one having its own unique evidence base to guide preventative and therapeutic options. Furthermore, the number of studies being published continues to grow exponentially.[47] As oncologists must be aware of advances in cancer diagnosis and treatment, it is not reasonable to expect them to also keep pace with advances in supportive care. Thus, to optimize symptom prevention and treatment, approaches are required to facilitate evidence-based clinical care. These approaches should be clinical practice guideline (CPG) development[48] and tools to facilitate implementation of CPGs into clinical practice, such as care pathways. They will lead to the standardization of symptom management and are likely to improve outcomes for patients, similar to that achieved related to protocolization of cancer treatment improving cancer outcomes.[49]

The current status of symptom intervention is likely poor in pediatric cancer care. For example, one study examined the medical records of 168 pediatric patients age 8-18 years who self-reported severely bothersome symptoms using SSPedi.[50] Interventions were uncommonly provided. The following severely bothersome symptoms were never treated: thinking or remembering things, changes in how your body or face look, tingly or numb hands or feet, changes in taste, or diarrhea. Failure to provide treatments when concerning symptoms are identified through PROs may be related to lack of awareness of effective strategies to manage symptoms.

Symptom prevention and treatment should be based on CPGs. CPGs are documents that include statements focused on facilitating health care–related decisions, with the goal of optimizing the care of individual patients.[51] Steps involved in CPG creation include conducting a systematic review of the literature and convening an expert guideline panel to balance the benefits and downsides of different treatment options to arrive at recommendations.[52] It is important that CPGs are developed using robust methodologies to ensure recommendations are based on available evidence. CPGs may make strong or conditional recommendations. A strong recommendation is made when the benefits of a treatment approach clearly outweigh the downsides or vice versa. In this situation, clinicians usually should adopt that action as a matter of policy (or not adopt it in the case of a strong recommendation against an intervention). Conversely, a conditional recommendation is made when the benefits and downsides of an intervention are closely matched or when there is considerable uncertainty about their estimates. In this case, institutions may choose to adopt or not adopt that intervention routinely or may leave decision making to individual clinicians and patients.

In pediatric cancer supportive care, it is common to hear the phrase "there is no evidence." However, unless one searches for CPGs, it is likely that clinicians will not be aware of CPGs developed to manage symptoms. One effort specifically conducted a systematic search for CPGs related to symptom management. It used a pragmatic approach to first evaluate repositories known to include methodologically appropriate CPGs. If CPGs were not identified, a systematic review was then conducted.[53] CPGs were identified for 14 of the 15 symptoms included in SSPedi, with the absence of a CPG directed at anger.

Thus, CPGs have been developed for many symptoms. However, they can be difficult to use directly to influence care. Furthermore, recommendations in CPGs require adaptation to individual institutions to consider available resources and culture. One mechanism to facilitate CPG-consistent care may be development, adaptation, and implementation of care pathways.

Development of care pathways. Care pathways are documents developed to improve clinical care that contain best practices with respect to the management of a group of patients.[54] We previously described one approach to care pathway conceptualization and development.[55] We envisioned that development of care pathways for institutional use could include two steps. First, the CPGs could be directly translated to care pathways, and this translation could include options for subsequent adaptation. This step would result in a single version of a care pathway template for each symptom. Second, the template care pathway would then need to be adapted for each institution. Consequently, there could be numerous adapted care pathways for each symptom.

The first step in creating a template care pathway was to first identify all CPGs focused on that clinical condition.[53] Once these CPGs were identified, recommendations would then be used to populate the care pathway template. The templates had a common structure across all symptoms consisting of prevention, assessment, and treatment sections. In populating the template, we created visual cues for strong vs. conditional recommendations to ease the process of adaptation by institutions. We also provided a list of possible resources that institutions could consider during the adaptation process. For example, psychosocial resources could include psychiatry, psychology, social work, art therapy, chaplaincy, child life services, music therapy, or recreational therapy. For relevant symptoms, each institute could choose from this list or could add additional resources dependent on those available at their institution.

Adaptation of care pathways. We previously described our experience in adapting template care pathways for symptom management at 10 institutions participating in a cluster randomized clinical trial comparing routine symptom screening and implementation of care pathways vs. standard of care.[56] In this early experience, we implemented the following four steps (Fig 2): preparation, initial care pathway

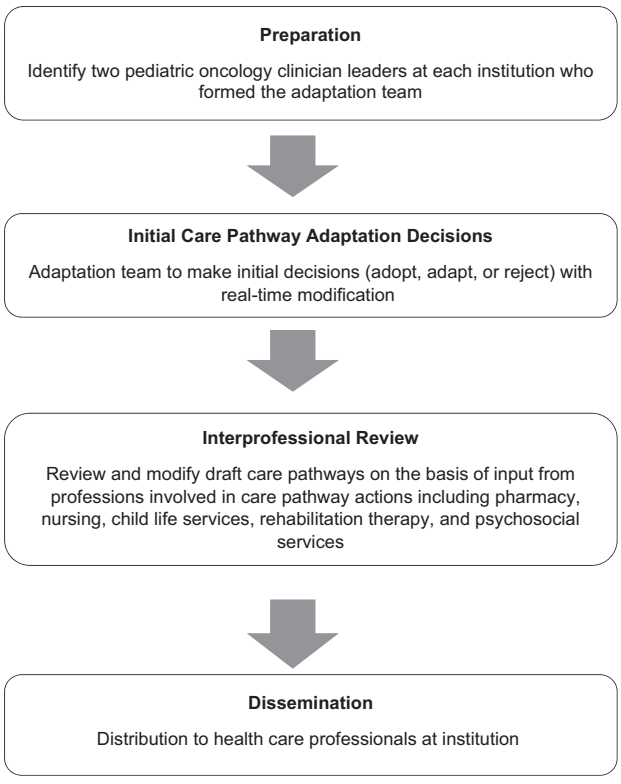

FIG 2. Overview of care pathway adaptation steps.

decision making, interprofessional review, and dissemination. The preparation phase involved identifying two pediatric oncology clinicians to lead the adaptation effort; they formed the local adaptation team. We chose two clinicians to reduce the work and ease the decision-making process, with a goal of making the procedure more feasible.

The second phase consisted of the main work of the adaptation process. For this phase, we worked through each template care pathway sequentially, where each template care pathway represented a single symptom. We reviewed each template recommendation and asked the adaptation team to decide whether to adopt, adapt, or reject the statement. We accomplished this process over a series of videoconference calls, and we modified the template in real time to enable the local adaptation team to reflect on the modifications made and further edit them as required. Examples of adaptations included modifying the language to reflect wording used at that institution, choosing first-line medications, describing medications using the brand name or generic name, and indicating consulting services or investigations. This process resulted in draft adapted care pathways that were institution specific.

The third phase consisted of interprofessional review. The adaptation team distributed the draft care pathways to representatives from disciplines involved in the care pathway actions such as pharmacy, nursing, and psychosocial resources. Their feedback was incorporated into the care pathways, and these were finalized. In this study, they were uploaded to a website named Supportive care Prioritization, Assessment and Recommendations for Kids (SPARK), which focuses on enabling routine symptom screening and encouraging CPG-consistent care for their management.[57-59] The final phase consisted of dissemination where the link was distributed to all health care professionals at that institution.

Future steps. Although the described process is one example of how to encourage evidence-based actions for symptom prevention and treatment, there are several areas that require investigation. First, although this approach standardizes symptom management at an institution, we do not yet know whether clinicians will follow their care pathways or whether these care pathways improve patient outcomes. However, we believe that standardizing supportive care on the basis of CPGs has distinct advantages in itself. Second, there are likely to be approaches that can improve clinician adherence to their local care pathways. Identifying the optimal approaches should be a focus for investigation. Third, although the described approach was feasible in that it was successfully accomplished at all institutions within the context of a trial, it was relatively labor intensive. Identifying approaches that are less resource intensive will be important to achieve a sustainable long-term solution.

CONCLUSIONS

PROs are important to pediatric patients with cancer and their families. Self-report should be emphasized wherever possible. Approaches to enable PRO reporting into routine clinical care and enable preventative and therapeutic actions for symptom management are important. Consequently, facilities should consider adopting the collection of specific PROs during routine clinical care and should identify approaches to implement CPG-consistent interventions to prevent and manage bothersome symptoms. These efforts will optimize quality of life for pediatric patients with cancer.

Fear of Saying No (FOSNO): Setting Boundaries With Our Patients and Ourselves

Monica S. Chatwal, MD[1,2,3]; Arif H. Kamal, MD, MBA, MHS[4,5]; and Jonathan M. Marron, MD, MPH[6,7]

overview

Cancer is an inherently complex and intense medical condition that often requires prolonged treatment and surveillance over years. Treatments can lead to frequent side effects and anxiety, requiring constant communication and follow-up with patients. Oncologists have the unique privilege of developing close relationships with their patients that evolve through the course of their disease. The advent of newer technology and the changing landscape of medicine have drastically altered how oncologists now manage patient needs. These changes have allowed for much quicker and closer communication but are not without personal and professional challenges. Some may wonder how accessible they can and should be to their patients—essentially, the boundaries they may place to protect their own identities and well-being. An oncologist might wonder how much of their personal contact information they should provide to patients and how often they should be available for questions and discussions when away from the clinic without impairing their relationship. Here, we define and explore the role of boundaries in medicine, and review common ethical dilemmas that oncologists face daily when trying to balance patient care and lives outside of medicine. Although we recognize there is no clear single solution, we will propose possible approaches to setting boundaries and potential pitfalls.

BACKGROUND

Some have said that to join the oncology profession is to answer a noble calling. This calling is embodied by supporting people at their most vulnerable, uncertain, and complex moments and cocreating a path forward that meets their goals, preferences, and values. This is all while balancing the intricacies of a complex health system inherently difficult to navigate, both as a patient and health care professional. Navigation of such a path is hallmarked by expertly balancing both science and art and refining these skills over a lifetime as a professional craft. Although much attention is given to honing scientific, clinical, and administrative knowledge of delivering cancer care, professionals should also allow for self-reflection. Although cancer care at its best is delivered by compassionate and available oncology professionals, how do we ensure that such an impassioned work force can professionally complete the duties of this noble calling while also thriving as individuals?

Discussions of oncology professionals' thriving in the current era starts with acknowledging some difficult truths. First, being an oncology professional is hard. It is hard because of the principle of volatility, uncertainty, complexity, and ambiguity (VUCA). VUCA was first introduced by the US Army War College after the terrorist attacks in 2001 to reflect on the rapid changing pace of the post-9/11 world.[1] They noted four areas of change: (1) unprecedent information generation, (2) the need to respond to multiple stakeholders, (3) inability to always anticipate changes or guarantee outcomes, and (4) less resources than ideally would exist. Sound familiar? Although on a different level of importance than national security, the everyday existence of an oncology professional is swimming in VUCA across many realms, from clinical decision-making to navigating professional development. Oncology is in a new era, with unprecedented growth in the number of treatment options, patients diagnosed with and surviving cancer, and employed oncologists. The former two highlight the immense cognitive burden placed on oncology clinicians. For example, the National Science Foundation estimates that nearly 2.6 million science and engineering articles are published annually across the globe.[2] If we assume that only 0.1% of those apply to oncology practice, it results in seven articles per day for each of 365 days for a person to read. The latter is important because for many newly employed oncology professionals, the locus of control for individual and practice decisions has shifted from clinicians to administrators and from communities to central hubs. Such evolutions in cancer care delivery require an intentional and dedicated focus on the oncology professionals' well-being not only as the means to an end but also as an end in and of itself.

BOUNDARIES 101

The American Psychological Association defines a boundary as a psychological demarcation that protects

PRACTICAL APPLICATIONS

- Oncology is a demanding profession, asking a great amount of those practicing in the field. The demands and complexities of oncology practice, combined with devotion of oncology clinicians, can make setting personal boundaries challenging, which can then lead to negative outcomes for clinicians (including harms to well-being, compassion fatigue, and burnout).
- Oncology clinicians can set boundaries while still meeting ethical practice standards as long as they do not abandon patients.
- Setting boundaries while still providing high-quality patient care can be challenging, and each individual oncology clinician may ultimately set personal boundaries slightly differently.
- Setting boundaries may ultimately allow clinicians to be more present and engaged while working, have more satisfaction with their work, and maintain personal well-being.

the integrity of an individual or group or helps the person or group set realistic limits on participation in a relationship or activity.[3] They expand that in psychotherapy this is an important limit that is usually set by the therapist as part of the ground rules in treatment and may be placed on topics of discussion or physical limits.[3] These definitions easily translate into medicine—to protect both the patient and the physician and their professional medical relationship. As oncologists, and frankly as individuals, most of us do not often consider setting ground rules in our professional practices (or personal lives), relying more on the inherent standards of social norms in communicating and interacting. Although with multifaceted cultures and socioeconomic backgrounds, there are no well-defined norms.

Boundaries are a vital form of individual self-preservation, both in personal and professional aspects of life. They protect our beliefs and values, preserve our priorities, and maintain our well-being. Dr Brené Brown describes them simply as "what's ok and what is not ok."[4] In his webinar on burnout for the American Medical Association (AMA) Steps Forward program, Dr Kevin Hampton describes boundaries as limits or margins that allow room for some give and take.[5] In her commentary, Mammoliti[6] compares the physician to a masterpiece in a museum and describes the ropes as boundaries used to protect and preserve the piece of art from eager visitors while still allowing them to enjoy the piece. We can argue that to functional as effective human beings, we must have some degree of boundaries. Boundaries create predictability, and in medicine where there are more often gray areas of uncertainty, this can provide security and sustainability.[6] Simply put, boundaries are enablers to being present and successful within, and between, many roles. The need for boundaries assumes the multidimensionality of a human being and the need to live as an authentic self—as an oncology professional and beyond.

Historical Boundary Standards

In the past, boundaries in medicine have been called on to highlight transgressions in professional behavior. Thus, the boundaries themselves were the edges of appropriate behavior, and focus on them was to call out the need for clear distinctions between professional practice and personal crossings.[7-9] Most previous literature also focuses on this topic of misconduct and is predominately in the form of commentaries, editorials, or opinion pieces. The AMA, for example, is quite explicit in stating that such relationships between physicians and patients are unethical, hearkening to the vulnerability of patients, the inherent power imbalance between patients and physicians, and the conflict of interest that would exist for a physician who also had a romantic/sexual relationship with their patient.[10] The AMA goes even further to state such relationships with former patients may also be unethical, as would similar relationships with key third parties, such as patients' family members or surrogates or others with a key role in the clinical encounter or in health care decision making.[10] By similar reasoning, the AMA also cautions against physicians treating themselves or their family members, owing to the complexity (and inherent conflict) in playing dual roles (eg, as clinician and relative), and to the lack of objectivity caring for a family member can cause.[10]

Where Do We Stand on Boundaries in Medicine?

To some degree, boundaries were a natural consequence of physical, geographic, and technological limitations and barriers. Distance between patients and medical centers limited how frequently they could be seen. The lack of more advanced means of communication including internet access and cellular devices meant that patients could only reach their provider through on call or after-hours phone numbers, pagers, and operator services. In some parts of the country, particularly rural communities, providers visited and cared for patients directly in their own homes (house calls). However, there appears to be a clear generational shift in medicine. Although house calls still occur in some parts of the country and in some practices and specialties, care has moved mostly to distinct health care settings. Now, the health care continuum transcends all locations. With laptops, cell phones, and messaging devices, time and location are no longer natural barriers. Telemedicine visits allow patients to been seen essentially anywhere at any time.

Imagine ending your clinic day, finishing notes, answering the last few emails, and logging out of the computer. Once you get home, you receive an email alert on your phone from a patient inquiring about medication side effects. Do you answer? Do you leave it to the next day? Do you forward it to your colleague on call or your nurse? These are all questions that may arise amid greeting family, preparing dinner, paying bills, or catching up with old friends.

There are few specific institutional guidelines on how to establish and maintain boundaries, most relying on generalized recommendations. There may also be misconceptions of what it means to have boundaries or guardrails for oneself. This does not mean that one is less professional or effective as a clinician.[11] Having limits allows for more emotional and cognitive flexibility. Having boundaries should not interfere with maintaining exceptional patient care. It should, however, create a healthier working environment and solidify the patient-provider relationship by leaving less ambiguity and uncertainty in communication and practice.

With shifting medical care, physicians are now taking on more off the beaten path tasks—records collections, prior authorizations (PAs), patient transportation through the hospital, and uploading outside imaging. By setting more clear boundaries and expectations, perhaps these tasks could be delegated to other members of the health care team. Some may argue that these tasks are being taken on because of a lack of support staff, resources, or finances, and by completing them, they can hasten patient care. Although they are fully capable of these tasks, we question: Is this the most efficient and productive use of physician time and resource? These are tasks that then detract from the physician's focus on patient care, and in oncology, these moments can be vital. Most of us want to do all we can for our patients, going above and beyond our call of duty, but eventually we may reach a point where we have no more of ourselves to give. In many ways, throwing all of yourself into patient care may mean you give less of yourself to everyone who needs you. In a recent viewpoint, Nadkarni et al[12] describe how accountability is a part of one's professional duty as a physician, but what often becomes overlooked is accountability to oneself. This idea of making sacrifices across many aspects of personal and professional life is not new, and being an advocate for our patients is a worthy part of our calling to medicine.[13] However, it is equally important to recognize our limitations and find a balance on the pendulum that swings between apathy and martyrdom.

More recently, experiences during the COVID-19 pandemic highlighted the importance of personal and professional boundaries. Medical professionals left the clinic or hospital while carrying home the looming threat of possible viral transmission to their families and friends. They left home each day with lingering concerns of childcare, pet care, job security, and adequate goods and supplies needed for home. There no longer seemed to be any safe spaces to decompress and reprioritize. The endless amounts of morbidity and mortality during the early periods of the pandemic further ignited the flames of burnout and declining mental health. A study published in *Mayo Clinic Proceedings* reported that rates of burnout in US physicians increased from 38.2% in 2020 to 62.8% in 2021.[14] These few years established the importance of physicians having guardrails—for security, safety, and well-being. We know that more resilient and emotionally aware physicians who can care for themselves are much more effective caregivers for their patients.[15-17] However, blurring boundaries across personal and professional settings and the lack of some communication restrictions may make work-life balance more difficult, contributing to compassion fatigue and burnout.[18]

ETHICAL CONSIDERATIONS REGARDING BOUNDARIES IN HEALTH CARE

Identifying how best to create boundaries while still providing high-level patient care can be challenging, and for many, it can represent a personal ethical dilemma. Is there a way to create such boundaries so that we can protect our own personal well-being while still providing the level of patient care that is so important in oncology? Furthermore, is it definitive that such boundaries will have a negative impact on the care we provide? Perhaps even more importantly, how can/should we ethically navigate the creation of these boundaries for ourselves while understanding that not all will necessarily support this? Although data are likely and sorely lacking in this area, this struggle has the potential to cause significant clinician distress. Furthermore, many clinicians express concern that such boundaries will affect patient satisfaction scores and/or how they are viewed/treated by their colleagues. As a result, guidance on the ethics of boundaries in oncology clinical practice is much needed.

In recent years, with the growth of many physicians' presence on social media, the AMA and the American College of Physicians have expanded their guidance regarding professional boundaries to the social media space.[19] In this realm, they argue that not only individual physicians must take care to maintain appropriate professional boundaries online but they also have a responsibility to alert their colleagues who they see acting unprofessionally online and even to potentially report such activity to appropriate authorities if the colleague does not take what is seen to be appropriate action.[10] Notably, the increasing presence of oncologists on social media in recent years has led to publication of several oncology-specific guidelines for professional social media use, but training on how to handle certain issues that may arise is still lacking.[11,18,20,21]

These standards might strike some as obvious or as a low bar, but they speak to the way that health care has changed in recent decades. Although we still occasionally learn of cases in which a clinician is found to be having an inappropriate relationship with a patient, the focus largely has changed to questions regarding how one can—or even should—maintain boundaries (with patients, with colleagues, with academia, etc) in the interest of one's own well-being, work-life balance, and safety. So then, in this modern consideration of boundaries, we must ask what is ethically obligatory? Just as not having a sexual relationship with a patient is an ethical obligation in the former conceptualization, what do we consider to be ethically obligatory today? Or, put in another way, what do we consider to be the low bar of boundary setting in modern health care?

Ethical Obligations

When considering such questions, it is important to distinguish what we consider to be ideal versus a minimum standard. In caring for a patient, there are often several reasonable treatment options, all of which meet a certain threshold of acceptability (eg, likelihood of survival with a favorable quality of life). In such settings, standard practice is not to obligate the option that is best but instead to choose one of these different options above the defined threshold by a process of shared decision making.[22]

Similarly, when considering boundaries, individuals are not expected (or obligated) to do what might be ideal for every patient or for their professional life. This ultimately would lead to a complete dissolution of boundaries, to loss of work-life balance, and likely to significant harm to individual well-being. Instead, as we further recognize the hazards of burnout, the importance of well-being and the challenges related to setting boundaries (both with patients and otherwise), individuals should consider what is ethically obligatory for themselves—the low bar when considering such boundaries.[23]

On this point, ethical guidelines and the law are quite clear. The ethical obligation—the low bar of professional boundaries—is nonabandonment. Modern Western ethical standards are clear that clinicians must not abandon patients, and legal standards, although variable state-to-state, similarly deem patient abandonment to be a form of medical malpractice.[24-27] Abandonment occurs when a clinician-patient relationship has been established, the clinician stops the treatment abruptly (without giving the patient time to seek an alternative care provider), and that cessation of care causes harm (or potential harm). Many hospitals and health systems provide guidance for their own clinicians and patients regarding this obligation of nonabandonment, often within the patient bill of rights or code of conduct.

That is not to say, however, that this obligation of nonabandonment requires either a loss of boundaries or personal integrity. Clinicians certainly are not required to continue to provide care to patients who are physically or verbally abusive, to provide treatments they find to be disproportionately harmful, to be available at all hours, or to take part in procedures to which they are personally opposed. Instead, as long as the patient's care can be safely transferred to another clinician/institution, these professional obligations can be met.

Finding the Ethically Optimal Boundary

So, if a complete lack of boundaries is at one end of the spectrum and patient abandonment at the other, where between those two poles lies the ethically optimal boundary that one can set for themselves? Unfortunately, this is a challenging task that likely varies from one individual to the next, depending on their own needs and values, as well as the circumstances under which they are trying to set these boundaries (eg, family considerations, institutional culture/support, clinical/academic focus, etc). Overall, most will likely wish to identify the way to set boundaries that allows them to provide the clinical care (and complete additional academic work, if applicable) that meets the standards of their own personal professional ethics while maintaining enough balance to be able to not only continue to fulfill that professional role but also to maintain job satisfaction and a globally fulfilling life.

BOUNDARY SETTING AND WELL-BEING

Nearly every stop along the oncology professionals' journey requires making choices between a professional aspiration and a personal goal. Akin to the Star Wars' Mandalorian way of life, for oncology professionals pushing limits to do more, better, and faster is our ethos—It is the way. Oftentimes pursing these goals means that personal needs are ignored—in college, a party is skipped to take a graduate school entrance exam; in residency or fellowship training, a birthday party is missed to conduct research; and as an attending, one excuses themselves from a dinner at the beck and call of a pager. These departures from normal life are so commonplace that oncology has its own culture. Professionals are expected to do one more thing, for a little bit longer with the tensile strength of a superhuman rubber band, stretching and bending with an unwavering agreeableness and affability. And to depart from this way of being can call into question work ethic and dedication from external parties and can force individuals to question their own suitability for the work. At the intersection of professional commitment, personal thriving is a boundary, which is only produced from intentional boundary setting.

Although the need for boundaries is universal, how those boundaries are created and used is individual- and context-dependent, an almost Goldilocks-like endeavor. For example, the types of boundaries required for a medical oncologist with on-call duties will vary from a shift-based oncology infusion

nurse. Similarly, they differ between a medical oncology fellow and a division chief. They also change through different phases of life and career. Despite different roles and expectations, all professionals should allow for the development and enforcement of personal and professional boundaries that balance common principles of respect of self, duty to others, and autonomy to decide. Critical to boundary setting is both a balance of duty and self-care alongside ensuring agency so that professionals play the leading role in developing, ensuring, and evaluating boundaries set for themselves. Fundamentally, as Simone's[28] legendary axiom is to suggest, the employer/institution does not love the employee back to the extent that sacrifices, rewards, and loyalty are equal. Professionals must own the discussion regarding setting boundaries for themselves with their employers, colleagues, and constituencies (eg, patients and clients). As can naturally occur, external forces with their own interests will pull for more from employees; gently discussing partnering around boundaries can ensure that both sides will achieve a win-win.

Importantly, boundary setting is not an event, but rather a process with continued refinement through feedback. Such feedback must involve data from the individual professional, their world, and their employer. Curiosity and intentionality are needed. Curiosity leads to questions like "What would be possible if I did less of XX and more of YY?" and "How might a close friend reflect on how I'm handling my competing demands?" Intentionality manifests as regular review of self-efficacy and effectiveness, and whether any tradeoffs in the development of boundaries are resulting in unfulfilled professional goals or leading to harm. Careful attention must be paid to balance the pendulum so that wide swings from apathy to martyrdom are avoided. For neither lead to professional nor personal success, and both are associated with an individual leaving an employer or the field altogether.

How Boundary Setting Promotes Trust

Frequently professionals worry that boundary setting will lead to missed opportunities. In the lay world, the term FOMO is used to denote fear of missing out. FOMO is the emotional response to the belief that important opportunities are being missed. In the oncology content, a more suited term may be FOSNO which is the fear of saying no. Similar worries to FOMO exist with FOSNO so that creating a personal boundary for oneself (by saying no) may lead to a sense of shirked obligation, guilt of not being agreeable, or fear of reprisal. For many, advancement into the upper echelons of clinical practice and administration has meant a certain agreeableness to increasing responsibilities, with a sense that delayed gratification will be a debt paid off at a future time. And naturally during times of training and learning, such approaches of saying yes many more times than declining an opportunity are valued and needed. This is because the process of evaluating an opportunity is also an important skill to attain as a learner. However, as one progresses in their career, a different decision model and accept/decline ratio may be needed. Such an evolved approach will serve to build trust, even as professionals may worry the opposite.

Zenger and Folkman[29] discuss in The 3 Elements of Trust the importance of consistency to developing trust with external parties. Readers with children need to only look as far as employing different consequences for children within a family for the same transgression—and the lobbying of unfairness that will follow—to understand the relationship between consistency and trust. More than words, people evaluate us by our actions. And those actions must be aligned with our stated intentions and must honor commitments and keep promises. Ultimately, trust bestowed by colleagues, patients, and our families/communities stems from our ability to follow through, with each stakeholder (eg, patient, colleague, and family member) evaluating the consistency of our actions from their lens. Thus, trust is hurt both when we do not respond to a patient with cancer in pain who was directed to page us when in extremis and when a clinical page takes us away from an anniversary toast expected by our parent—all while striving to be an excellent clinician and loving child.

Many times, trust is lost when we fall victim to the fundamental attribution error. Oversimplified, this results from individuals judging themselves by their intentions and others judging them by their actions, take for example, the well-meaning junior faculty member who agrees to write from scratch a comprehensive review article for a special journal series coedited by her mentor. Because of a prescheduled vacation, caregiving responsibilities of a parent, and rounding on hospital service, the one-month deadline comes and goes without completion of the manuscript. The junior faculty member had intended to demonstrate agreeableness, being a good mentee, and a team player. However, she is judged by her actions, and the relationship between herself and her mentor is strained, and trust is broken. In this, we must be mindful that good intentions of being everything to everybody is laudable in theory but oftentimes leads to disappointment in follow through. Such disappointment is understandable, and in some way, it may be inevitable. However, such a scenario is yet another reminder of the importance of sometimes saying no.

Keys to Boundary Setting

Oncology professionals are challenged with embodying multiple roles during their career. Rarely is one only a clinician, only an administrator, or only a researcher. Commonly, lines blur, responsibilities get added or taken away, and competence is awarded with further roles and work. We have found that through this process, the following five

activities help build consistency of action and trust in behavior. Table 1 further explores common issues in boundary setting and recommendations.

Be intentional with intentions. Closer alignment of intentions to planned actions requires knowing one's own intentions for professional advancement and personal success. This requires first knowing the coins of the realm that lead to success. For example, in academic medicine, the three coins are the 3 R's—relationships, resources, and results. Put another way, who you know and work with, what grants and other capital you have, and what publications, presentations, and other deliverables you disseminate. For our mentees, we recommend that any opportunity they consider must contribute to at least two of these. Such a consideration is dependent on the person and the situation. For example, a fellow who is looking to secure a faculty position at his training institution and whose career interest is becoming a pancreatic cancer expert may strongly consider an opportunity to join the health system pain control task force that has the division chief as the task force chair (pursing a relationship with her) and a GI oncologist as member (to offer to work with the faculty member on a QI project commissioned by the task force). With these objectives clear and appropriate planning to attend the meetings, the oncology fellow has the critical intentionality to participate in such a group. Frequently, opportunities are compelling because of mere FOMO, with only one of three coins attained. Self-reflection will reveal that this happens more than we may appreciate.

Consider the rule of 1Os. In oncology, everything seems important, urgent, and necessary. And yet, few issues are long-lasting. To achieve a sense of objectivity, we like to incorporate a rule that considers whether an issue will remain top of mind in 10 minutes, 10 hours, 10 days, 10 weeks, 10 months, or 10 years. Such a frame of thinking provides perspective regarding the cognitive and emotional bandwidth an issue should take and whether a new mental boundary is needed to deprioritize something in the

TABLE 1. Examples of Common Boundary Issues and Recommendations

Examples	Recommendations
Time	Set time limits For patient encounters, conversations and encounters with friends, checking work-related emails and messages outside work, administrative tasks Use a timer to monitor time more objectively Focus on 3 Rs—relationships, resources, and results to prioritize time and activities
Communication	Outline a communication care plan Clear and direct expectations on how to reach you, when you can be reached (including days and times), instances on when to use this mode of access versus others, if other team members should be included This communication plan can be for both patients and colleagues
Being honest about priorities, abilities, and limitations	Say no (respectfully) To seeing repeatedly late patients (without an appropriate excuse) or patients who are physically, emotionally, and verbally abusive To repeatedly completing tasks that interfere with direct patient care To an opportunity or task that is nonurgent and pulls you away from a commitment or obligation outside work
Being intentional and consistent	Stick to the boundaries and expectations you set Try to avoid contradicting your own expectations and boundaries. If you say you do not want to be contacted after a certain time and will not answer messages, do not respond to messages past that time Delay sending the email—not all messages need an immediate response Compare practice data to benchmarks, such as HER usage after hours
Empower/educate colleagues, junior faculty, and trainees	Vent and provide a safe space for self-reflection for yourself and others Inspire other oncology professionals, particularly trainees and junior faculty, to comfortably set boundaries without guilt or fear
Advocate for change	Provide direct, specific feedback to your institution and help in the process of developing better guidelines/safeguards to suit provider needs

moment. For example, a medical oncologist may receive an autogenerated email from the clinical practice office that patient satisfaction scores from the last month are in, and he received 4.9 of 5 from 85 patient surveys. Although this communication may risk the oncologist being distracted in thinking about why a perfect 5.0 did not occur and not mentally present during a family meal, the rule of 10's may help. In this case, likely the time effect of the less-than-perfect score will likely not affect the oncologist for more than 10 days (as new scores will come in) and thus with perspective, the oncologist can focus back on his family.

Have everything. Oftentimes boundaries are difficult to accomplish because of seeking it all, a mystical future state where a person has everything, everywhere, all at once (not to be confused with the Oscar-winning film). In truth, many highly motivated and accomplished persons can achieve excellence in every aspect or domain of their career but likely not all at one time. Personified, this is the adage you can have it all, just not all at the same time. We recall mentors who are world-renowned thought leaders in oncology and whose publication cadence slowed during the critical years of child-rearing. When the children left home, the investigator could push harder on the publication gas pedal with the newly found time afforded by fewer baseball games and theme park visits. In truth, careers are marathons, not sprints. The average retirement age for physicians is nearly 70 years, which means decades of being in the same profession (a feat accomplished by few outside of medicine and certain professional fields).[30] Rarely are doors permanently shut, and as referred to above: Do missed opportunities fall in the 10-year category?

Have work/life balance mentors. Many oncology professionals recognize the benefits of having career mentors who focus on professional development, skills attainment, relationship building, and overall career guidance. And yet, few have an identified person in their life who is asking questions like what are you stopping to take on that new work?, is that something you could do later?, or what parts of your life outside of work may be affected by that new work responsibility? For some, one mentor can simultaneously focus on the brake and the gas, the work and the life. But for many, it takes those who are not conflicted by success on one side to genuinely guide about the other. In our experience, many oncology professionals surround themselves with a mix of career and work/life mentors to bring several perspectives and inquisitive questions to their mentee's portfolio of obligations.

Find/review/embody meaning and purpose. Inherent to the oncology profession is an immense privilege from standing side-by-side with those experiencing a life-changing diagnosis and lending a hand. All in the profession have felt a profound calling, informed by personal or professional experiences, that required harnessing significant time and energy to improve the human experience. To temper the importance and sacrifice would be disingenuous to the journey and the cause. Yet, in bringing our whole selves to this work, we must be fueled by experiences outside of work. William Osler was an avid reader of philosophy and biographies. Anthony Fauci runs marathons. Cliff Hudis surfs in the summer and skis in the winter.

CONCLUSIONS

Medicine is a profession of caring—caring for others and caring for ourselves. At the end of the day, we are all on the same team, working toward the same ultimate purpose of patient care. And yet that process of caring, of being proximal to the suffering of others, can leave a residue on us. It is described by the analogy of standing next to a waterfall, and not having time to dry off. If the waterfall is the distress to which we bear witness, why should we not be intentional of stepping away and creating a boundary between the waterfall and the dry space a little bit away? We challenge all oncology professionals to take a moment of self-reflection and consider their limits—for their patients and loved ones, but mostly for themselves.

From Boring to Bravo! Using Learning Science to Create Memorable Presentations

Jennifer E. Schwartz, MD, FRCPC[1]; Sam Brondfield, MD, MAEd[2]; Katherine Walsh, MD, MAEd, FACP[3]; and Rami Manochakian, MD[4]

overview

The practice of oncology continues to evolve over time. Educators find themselves in a position where they are no longer able to teach a topic in its entirety. Moreover, the rapid expansion of information available through research and discovery in the field of oncology makes it difficult for learners to process the constant barrage of new content. Lecturers continue to impart knowledge using didactic techniques, often trying to include as much material as possible in the time permitted. The question becomes: In the face of an impossibly large field, how can one assist learners in learning, and retaining, what is most important? The science of learning continues to develop, and we now recognize that there are ways to teach that optimally facilitate the retention and application of knowledge. By using these strategies, educators can make it easier for learners to absorb and retain key information. This article will touch upon several such techniques: cognitive load optimization, analogy, contrasting cases, elaboration, and just-in-time telling. By applying these methods to didactic presentations, educators can ensure that their lessons are heard, understood, and ultimately transformed into something unforgettable.

OPENING SCENARIO

A lecturer is excited to deliver a talk to oncology fellows about colon cancer. This single lecture is the main didactic session dedicated to colon cancer within the whole fellowship curriculum. The lecturer is determined to include as much information as possible to ensure that everything is covered. After many hours, they produce slide after slide, replete with clinical trials and Kaplan-Meier curves, and while the text is small, they are pleased that the fellows will have all the data!

The morning of the lecture, the fellows sip their coffee and eagerly await the teachings of one of their favorite clinic attendings. Five minutes into the 60-minute talk, the fellows' eyes start to glaze over, and they start checking their phones. Another 5 minutes pass, and some eyes are drifting closed. The lecturer ponders: Why do the fellows seem so disinterested? They love learning from me in clinic! And I put so much work into preparing this lecture! What went wrong?

In today's fast-paced world where attention spans are mere seconds to minutes, it can be challenging to captivate learners for the duration of an entire lecture. Moreover, the rapid pace of new scientific and clinical discoveries in oncology can be overwhelming. Educators are no longer in a position to teach the entire field of oncology and are thus faced with teaching learners how to synthesize and apply knowledge within a rapidly evolving landscape. Medicine often finds itself using old methodologies of information dissemination including PowerPoint presentations with seemingly endless content for learners to absorb in a brief period. Conferences use darkened rooms with hours of information delivery in the hopes of sharing important data for clinicians to apply within their own practices.

The study of how people learn has evolved over time. For example, although individuals can learn through multiple modalities, care must be taken when combining delivery systems. Reading written words on a slide is associated with diminished recall, simply because the simultaneous task of absorbing information by reading and listening limits the learner's ability to do either one well.[1] As another example, while learning objectives can set the stage at the beginning of a session, additional strategies are needed to help learners identify the key learning points that they should recall at the session's conclusion.[2]

As you will read, an understanding of learning science can improve an educator's ability to disseminate information to learners effectively, thereby promoting their ability to retain and apply knowledge. By determining your session's desired outcomes, you can choose the tools that will be most effective for information delivery. Are you looking to further knowledge acquisition and memorization? Ensure conceptual understanding? Or have learners problem solve? By starting with those basic questions, you can inform your chosen approaches.

For example, when asked to recall a list of words, subjects remember those at the beginning and those at the end.[2] You can take advantage of these primacy and

PRACTICAL APPLICATIONS

Tips to make your presentation more memorable:

- Avoid overloading slides with information and emphasize key teaching points.
- Avoid distractions so learners can focus on important content.
- Use contrasting cases to highlight key differences between concepts and analogies to emphasize similarities. These help learners make connections with known elements in their long-term memory.
- Expose learners to problem-solving before a lecture; this will help with their conceptual understanding.
- Create a space of psychological safety which will promote learning, elaboration, and interaction, leading to greater comprehension.

recency effects by selecting which information to emphasize at the beginning and end of your presentation. The take-home points can be cemented at both of these opportune moments. If there is key information that your audience must recall, you can assist them in meeting that goal simply by adjusting the timing of your information delivery.

Our ability to integrate information into long-term memory is optimized when such principles are used. While this article will focus specifically on the transformation of a didactic talk, it is important to recognize that this information can be applied in numerous teaching settings including classroom lectures, ward rounds, and small group sessions. By applying the elements that make the most sense for your session type and desired learning outcomes, you can improve the learning experience and achieve those outcomes with greater ease.

COGNITIVE LOAD THEORY AND ITS APPLICATION TO TEACHING

The well-intentioned, knowledgeable, and popular teacher described in this article's Opening Scenario could have engaged their learners more effectively with increased attention to cognitive load (CL). CL theory (Fig 1), originally described in the 1980s by John Sweller[3] and now one of the most commonly referenced learning theories, depicts working memory as a bottleneck for learning. The working memory can only process limited amounts of information at a given time, so much of the sensory input that enters the working memory is quickly forgotten while only a small subset is encoded into long-term memory for later retrieval. The process of encoding information from working memory into long-term memory storage is called learning. For someone to learn, their working memory must have sufficient capacity to process the desired information. If working memory capacity is exceeded before the desired information enters the working memory, the information will not be learned.

CL is the mental effort required to perform a cognitive task, such as learning from a lecture.[4] If a learner's CL exceeds their working memory capacity, learning will not be optimal. Learners encounter three sources of CL during a cognitive experience such as a lecture (Fig 2): intrinsic load (IL), extraneous load (EL), and germane load (GL). IL is the mental effort that the *task itself* requires sitting in the classroom (in-person or virtually), listening to the lecturer, and viewing the slide content. A key example of IL is the level of the lecture's content. A straightforward and simple lecture intended for senior fellows will impose a very different amount of IL for a junior resident. IL should be *optimized* such that early learners encounter relatively simple learning tasks while advanced learners can handle more complex learning tasks. EL is the mental effort required to navigate *distractions* unrelated to the lecture's content. Examples of EL include slide elements (eg, excessive animation), presenter elements (eg, excessive gesticulation or saying "umm" frequently), and external elements (eg, noise in the room or texts/e-mails related to patient care). EL should be *minimized* as much as possible. GL is the mental effort left over after IL and EL are accounted for that can be devoted explicitly to *learning*. GL should be *promoted* to enhance learning.

Educators can use strategies to optimize IL, minimize EL, and promote GL.[5] To optimize IL, educators should target teaching to the intended learner's level. For example, an early first-year fellow may not yet know enough about the principles of colon cancer diagnosis and treatment to be able to internalize and critique multiple clinical trials. Thus, it may behoove a lecturer to limit the amount of clinical trial data presented to early learners of oncology and focus instead on key principles. Similarly, limiting the number and scope of learning objectives to be achieved during a lecture will help focus learners on the key points to take away. The amount of information to be included in a lecture should be reasonable for the time allotted rather than attempting to fit

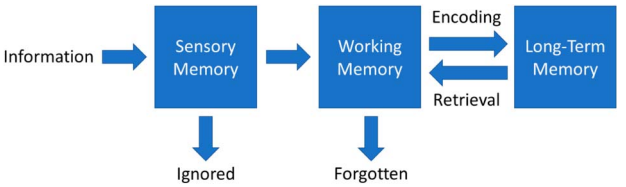

FIG 1. How incoming information is processed according to cognitive load theory.

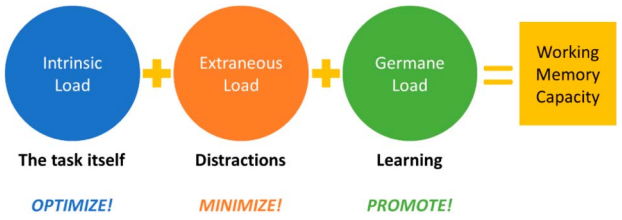

FIG 2. The three sources of cognitive load, their definitions, and associated teaching goals.

an excessive amount of content into a limited timeslot, which will result in a rushed presentation and/or overly packed slides. It is better to present learners with less information that they can actually learn, rather than overloading their working memory with excessive data such that little is retained.

To minimize EL, educators should make efforts to reduce or eliminate learner distractions whenever possible. These distractions may be elements a lecturer can control, such as eliminating redundant text or unrelated visuals on slides, making sure the lecturer's e-mail is closed so it does not make sounds during the presentation, or reducing the occurrence of a lecturer's distracting movement such as a nervous foot tap. External factors such as noise may be more difficult to control, but simple interventions such as closing the door to the room to reduce hallway sounds and asking learners to silence their phones can be helpful. Systemic interventions, such as fellowship programs providing clinical coverage for fellows during educational time to eliminate distracting clinical communications, can be challenging to implement but make a large difference in EL.

To promote GL, educators should use strategies to prompt learners to engage with the key learning points whenever possible. Examples include summarizing key points repeatedly, visually highlighting key points on slides, incorporating active and interactive learning opportunities such as polling the learners and facilitating group discussion, connecting new knowledge to information the learners have seen before, and applying learning to clinically relevant scenarios. Incorporating clinical cases with interactive questions and discussion into a lecture will enhance learning beyond what a series of slides with clinical trial data can do.

So what could the lecturer from the Opening Scenario have done from a CL perspective to engage their learners more effectively while teaching about colon cancer? Instead of trying to include excessive content in the talk, they could have boiled the lecture down to three concrete learning objectives covering, for example, principles of staging, treatment, and prognosis. They could have focused their slides on key principles and take-home points, supported by a smaller number of figures, instead of presenting many Kaplan-Meier curves in a row. They could have asked a colleague for feedback on their talk ahead of time to catch any distractions because of their slides or presenting style that they may not recognize. Perhaps most importantly, they could have incorporated clinical cases with interactive questions to promote discussion and application of the material. Preparing and delivering a lecture with attention to CL takes more effort on the part of the educator but pays off for the learners who will retain the information and apply their learning to patient care.

HOW TO ACE TEACHING THROUGH ANALOGY, CONTRASTING CASES, AND ELABORATION

There are many different learning science principles that, when implemented properly, can enhance the teaching and learning experience. In this section, we will focus on three that are essential for creating an effective oncology presentation that is easy to understand and follow.

Analogy

Analogy is defined as drawing a comparison between two things. When applying this concept within the educational environment, it requires the identification of similarities between two or more dissimilar examples.[6,7] Depending on the level of learner, the context and the topic of the presentation, there are different methodologies that may be considered.

In the first approach, the educator remains the guide and facilitates comprehension by creating a comparison with a familiar situation or process and then clearly explaining the application.

For example, as Katz describes, when trying to teach about the lymphatic system and its physiologic implications, one might consider comparing it with an alarm system. Just like the wiring system and sensors of an alarm system, so too the lymphatic system has channels and lymph nodes that permit the body to detect an infection or injury and mount an immune response. Further explanations may add that lymph nodes are like detection stations for the system, and this can be a path down in which cancer cells may easily travel.[8]

In the second methodology, one can ask learners to generate their own explanations on the basis of a given analogy. As an example, consider the biology and mechanisms of action of oncology drugs, specifically, immune checkpoint inhibitors. Consider having two aligned figures, one with an image of a brake pedal with a foot being lifted off the brake and a second with a cancer cell with PD-L1 on the surface along with an immune T cell with PD-1 on the surface. After providing these images in parallel, one can then ask learners to explain the mechanism of action of immune checkpoint inhibitors. By analyzing the analogous foot and brake pedal,

learners can conceptually understand that immune checkpoint inhibitors release the brakes so that the immune system can attack the cancer cells.

This self-generation of the explanation, when used with analogy, is considered an even more effective learning tool. Engaging learners in this way not only teaches them to think in analogies but also allows them to analyze the material deeply and facilitate their comprehension. Benjamin Franklin said it best: "Tell me and I forget, teach me and I remember, involve me and I learn."

While analogy helps the learner comprehend a new concept through comparison with a known entity, teachers must be careful to avoid anchoring bias. It can be difficult for a learner to understand that while two situations may have multiple similarities, they are still different. We explain this further in the next learning principle, contrasting cases, which focuses on learning through the appreciation of the differences between two concepts.[7]

Contrasting Cases

As the name implies, contrasting cases identify differences between two or more somehow similar examples or concepts. In teaching, contrasting cases highlight distinctive features of a particular concept and help the learner understand these distinctions by focusing on their relevant differences.[6,7]

With the rapid evolution of the field of oncology over the past two decades, the learning principle of contrasting cases has become one of the most useful tools. In a world with multiple therapeutic options and treatment decisions that depend on many variables, guidelines and management pathways can be overwhelming. As oncology educators, we must guide our learners to discern the key distinctive features that govern therapeutic decision making. Contrasting cases permit learners to understand these critical elements and facilitate the comprehension of what may seem to be abstract concepts.

Table 1 lists some examples of contrasting cases. Each example can be implemented using tables, figures, or other means. As with analogies, contrasting cases can be guided by the instructor or learners can be asked to develop their own contrasting cases. By having learners recognize key differences and determine the impact on an outcome, contrasting cases create deep understanding.

Ultimately, whether asking learners to recognize similarities between a new concept and a familiar example (analogy) or distinctive differences between similar examples (contrasting cases), educators will find the application of these techniques straightforward (Fig 3). While useful in lectures, these principles can also be integrated into prework (see the Just-in-Time Telling section) or postlecture assignments after a presentation to ensure learners have grasped key concepts and their implications.

TABLE 1. Examples of Using Contrasting Cases in Oncology Presentations

Teaching TNM classification: how to show a learner that T can mean multiple things	T in colon cancer means depth of invasion *v* T in breast or lung cancer means tumor size
Teaching the impact of cancer staging	Two cases with similar clinical presentations: Case 1: TNM stage 1 with curable treatment options Case 2: TNM stage 4 with palliative treatment options
Teaching the differences between two oncology drugs for one type of cancer	Drug A: indication, toxicity, dosing Drug B: indication, toxicity, dosing

Elaboration

Elaboration is defined as making connections between new information and prior knowledge to improve memory. In the context of teaching, elaboration helps encode new knowledge and transfers it from the working memory into long-term memory where information can be retained and retrieved at a later time.[6,9] Finding ways to connect new material to prior known information, even if seemingly unrelated, can help improve transfer of the new information into long-term memory.

Elaboration can be accomplished through numerous mechanisms. For instance, one might group similar elements together to facilitate their recall or discuss a connection between new information and knowledge the learners have covered previously. Elaboration is analogous to building a house: A strong knowledge base forms the foundation on which new information can be added.[9,10]

For elaboration to be effective, it must be tailored to the learner's level. The strategies used in an oncology presentation for medical students will need to be different than those provided in a presentation to an audience of certified

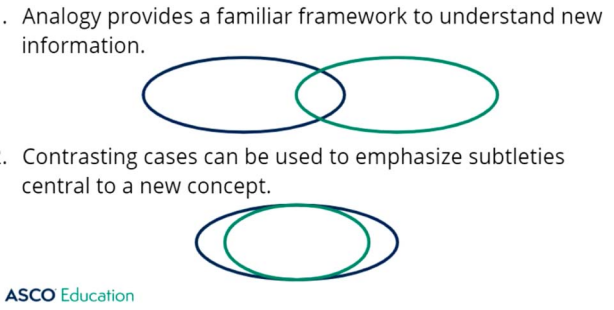

FIG 3. Difference between the principles of analogy and contrasting cases.[7]

oncology providers. Table 2 lists some known and suggested examples of elaboration strategies that a speaker can use to enhance their presentations for a variety of audiences.[9]

JUST-IN-TIME TELLING: MEETING YOUR LEARNERS WHERE THEY ARE

Opening Scenario Revisited

The beloved clinic attending applies learning science to their lecture and revamps their presentation to optimize CL and adds case-based scenarios with audience response questions. The learners participate a bit more to answer the audience response poll questions, but many responses are incorrect. The teacher reviews the postclass survey, and the students rated the relevance of the content covered as average with some below average scores as well. The teacher seeks additional feedback.

In this section, we will discuss the learning science principle of just-in-time telling (JiTT). This principle, when used to design a session, affords learners both an appreciation for the relevance of a topic to their training and useful and applicable knowledge.[6] The scenario described above illustrates a challenge that can arise when learners have not experienced a particular clinical situation in advance of the didactic session and therefore may not perceive how the didactic content will be applicable to their clinical practice.

JiTT requires learners to have experienced the content first before hearing or discussing it in a didactic session.[6] This type of learning happens organically during clinical rotations where the learner sees a patient on their own and develops an assessment and plan before presenting to their attending. Applying this learning science principle to a classroom setting is more challenging but can be adapted and implemented with preplanning. The three steps that can be applied to facilitate conceptual understanding using JiTT are (1) designing a prework exercise to provide experience with the content in advance of class, (2) creating a safe learning climate right at the beginning of the session, and (3) selecting interactive experiences that will enhance engagement and learning (Fig 4).

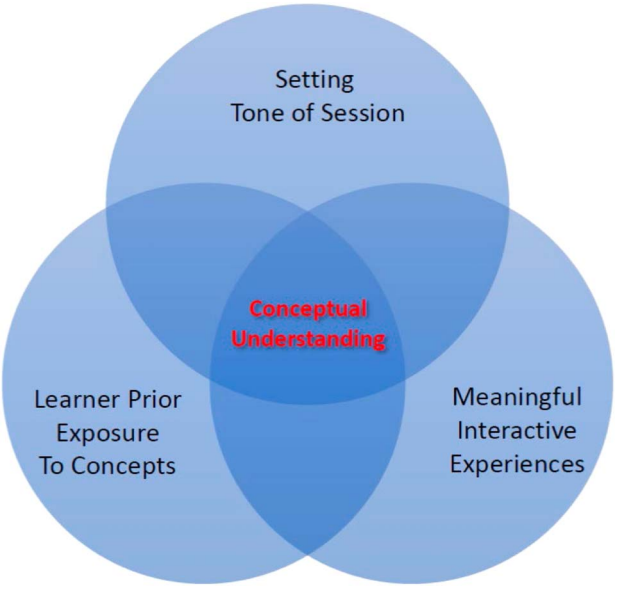

FIG 4. Key elements required to promote conceptual understanding with just-in-time telling. Bottom-left circle: Step 1 takes into account the prior knowledge learners bring to the session and the time they have available for prework. Top circle: Step 2 represents the need to directly talk to the learners about learning climate and create a safe space to make mistakes. Bottom-right circle: Step 3 emphasizes the goal of creating meaningful interactive experiences that enhance learning and help learners apply the knowledge. The goal of conceptual understanding represented in the center of the diagram is learners walking away from the session with more usable knowledge and an appreciation for why it is important.

Step 1: designing the prework. This step is important for meeting the learners where they are because the amount of time available for prework will vary based on the stage of training. The flipped classroom is an established approach that works well in settings such as medical schools where learners have protected time to read and analyze information in advance of the session.[11] By contrast, assigning a series of flipped classroom exercises to a fellow on an intense inpatient rotation would run the risk of increasing CL and being perceived as a burden. In our teaching scenario where the audience consisted of clinical fellows, the teacher could instead send a few discussion questions ahead of time to prime the fellows in advance of the class discussion with minimal preparation time required.

An additional point to consider is that learners at the same level of training will still have variability in their experiences and prior knowledge.[12] There may be more consistency in the setting of a fellow lecture on colon cancer, but having an awareness that not all fellows will have had the same exposure to colon cancer is important.

Step 2: setting the tone. Taking time to establish an inclusive and safe environment at the beginning of class is important to encourage participation. It is a standard part of PowerPoint presentations to start with a learning objectives

TABLE 2. Examples of Elaboration Strategies in Oncology Presentations

• Grouping similar ideas into categories that are familiar to learners
• Reviewing a new US Food and Drug Administration drug approval within the context of the standard of care
• Having learners relate new concepts to their own experiences after a presentation
• Using familiar mnemonics or acronyms to assist in memorization of new material

slide, but a teacher may not always pause and set the tone for interactions during the class. One strategy to encourage participation is to explicitly state that the most important aspect you are looking for is learners actively engaging with the clinical cases being discussed and sharing what they know, rather than placing the emphasis on giving the right answer. If the learners fear that they will be judged for giving a wrong answer, they will hold back from participating when they are unsure.

Establishing a safe learning environment will help learners be willing to ask questions and discuss content that they are still trying to master. As depicted in Figure 2, not all content that learners are previously exposed to will make it into long-term memory, and the learners will realize what they have not fully understood as they try to generate answers to discussion questions in class.

Incorrect answers from learners are helpful for guiding teachers to focus on areas where the class needs more practice. One strategy to make learners feel comfortable giving an incorrect answer is to provide a contrasting case in which the answer they provided would be the correct answer.[6] In the business literature, the concept of psychological safety has been described as benefiting the whole team, and in our educational environment, it will similarly benefit the whole class in moving toward conceptual understanding.[13]

Step 3: designing interactive experiences. The first two steps focused on the preparation for the class discussion, and now our focus will turn to optimizing the interactive classroom activities. A commonly used approach is adding board review questions to a fellow lecture. While this does add interaction and can be used in a pretest and post-test manner to gauge understanding of key points, it is not guaranteed to generate discussion. In our scenario, the learners answered the poll question on their phones but did not engage in further discussion of the answers.

It can be tempting to stay with traditional board review multiple-choice questions since they are readily available and represent a format familiar to teachers. However, this strategy alone may not be enough to spark discussion. In an ideal situation, all learners would have protected time to read and prepare for class, but for clinical fellows, time is often limited. An alternative approach faculty can consider is carving out protected time during the session for learners to read a key article or work through case scenarios. The case-based learning format could be used to give the learners opportunity to grapple with the content during class and work through cases with faculty guidance.[14] While some case-based learning experiences are longer, even a brief time dedicated to learners working on a clinical case scenario would aid in their understanding of the didactic content.

Finally, faculty can ask learners questions in class to facilitate interaction and elaboration, such as what is something you have seen in clinic or on the wards related to this? These types of questions do not have a right or wrong answer, and faculty can adapt their session on the basis of learner responses.

TABLE 3. Picking the Right Learning Science Tool

Opening Scenario Revisited

The lack of response in this scenario could have been related to any of the three steps. The faculty member reflected afterward that they dove right into the learning objectives and content without clearly establishing a psychologically safe learning environment. The faculty member also noted they were uncomfortable with the silences and did not pause long enough for the learners to generate a response.

Adding interactive exercises is a good strategy, but if the exercise is not well designed to promote interaction or not accompanied by a tone of psychological safety, silence can ensue and detract from the session. By taking the time to allow learners to wrestle with the content before a didactic talk, and by creating a safe space and interactive opportunities in the classroom, educators can improve learner understanding and recall of key concepts (Fig 4).

CONCLUSION

The incorporation of learning science can truly transform your presentations. By applying these straightforward principles, you are helping learners focus on achieving a deep understanding rather than forcing them to work harder only to achieve the same, or inferior, results.

Remember the importance of optimizing CL to improve the transfer of new information into long-term memory. By minimizing extraneous elements and keeping IL manageable, your learners will be able to process and appreciate the most important pieces of information without losing them in the fray. In today's world of oncology, where an endless amount of information is available to learners with only a few clicks of a mouse, the emphasis of education must be on facilitating distillation by highlighting the most important content.

- Keep the information on slides limited.
- Avoid complexity of figures.
- An image while you speak is worth a 1,000 words.
- Limit distractions.

When considering *analogy* and *elaboration* to communicate new information, remember that associating new concepts with elements that are already familiar will improve understanding and recall.

- Relate new information to elements that are already familiar.
- Use situations that allow learners to make associations they can easily comprehend.
- Help learners to organize the information into groups or to use meaningful acronyms.

When applying knowledge to a different scenario, *contrasting cases* can facilitate understanding. Providing examples that are almost but not quite the same highlights the subtle differences, thereby augmenting understanding. However, changing multiple elements can be confusing and dilute the key message.

- Discriminate one element at a time.
- Allow learners to understand the impact of a key difference or feature.

JiTT, which upends traditional expectations for classroom teaching, provides learners with information beforehand followed by an in-class application exercise. When learners are forced to problem solve in class on the basis of assigned prework, they develop context for the content and an improved ability to apply their new knowledge.

- Ensure learners have contact with the material before the classroom discussion.
- Create a space of psychological safety to facilitate open discussion and interaction.
- Create meaningful interactive experiences.

Our closing message is simple: By using appropriate educational tools grounded in learning science, you will assist your learners in transferring new information into their long-term memory. You will make it stick. Your learners will then be able to recall key information and apply it to future scenarios such as clinical care. Consider your learners' level of training and your desired learning outcomes and then pick the best tool(s) to accomplish your goals (Table 3). As we look to the future of oncology, we must recognize that our efficacy as clinicians, researchers, and educators is measured by our ability to adapt and integrate new knowledge as it becomes available. Learning science principles are critical for the optimization of teaching and learning in today's environment of unbounded oncologic discovery. As educators, we must incorporate these principles to help learners navigate this vast field. It all starts with you.

Structural Sexism and Cancer Care: The Effects on the Patient and Oncologist

Bridget P. Keenan, MD, PhD[1]; Elizabeth Barr, PhD[2]; Elizabeth Gleeson, MD, MPH[3]; Caprice Christian Greenberg, MD, MPH[3]; and Sarah M. Temkin, MD[2]

overview

Despite progress toward equity within our broad social context, the domains of gender as a social, cultural, and structural variable continue to exert influence on the delivery of oncology care. Although there have been vast advances in our understanding of the biological underpinnings of cancer and significant improvements in clinical care, disparities in cancer care for all women—including cisgender, transgender, and gender diverse women—persist. Similarly, despite inclusion within the oncology physician workforce, women and gender minorities, particularly those with additional identities under-represented in medicine, still face structural barriers to clinical and academic productivity and career success. In this article, we define and discuss how structural sexism influences both the equitable care of patients with cancer and the oncology workforce and explore the overlapping challenges in both realms. Solutions toward creating environments where patients with cancer of any gender receive optimal care and all physicians can thrive are put forward.

DEFINING STRUCTURAL SEXISM

Over the past 50 years, the availability of educational and employment opportunities for women has led toward societal advancement and gender equity.[1] Despite advances in the understanding and treatment of cancer, disparities persist across cancer care and the oncology workforce.[2] Structural sexism or systematic gender inequality in power and resources influence and perpetuate inequities for women within the health care system.[3] Defining certain terms surrounding structural sexism is essential to understand the concept. The terms sex and gender are often conflated but refer to distinct categories. Sex and gender are multidimensional constructs in which sex refers to anatomical and physiological traits (sex traits) and gender is a social construct on the basis of expressions and social and cultural expectations associated with sex.[4] As a social and structural variable, gender encompasses multiple domains beyond gender identity: gender roles, gender relations, and power.[4] Structural sexism can be measured at the macro, meso, and micro levels. The macro level refers to institutional sexism such as policies, cultural norms, and distributions of resources; the meso level refers to patterns of behavior and organizational practices; and the micro or individual level refers to the gendered perception of self.[3]

Both patient care and physicians' careers are negatively affected by structural sexism (Fig 1). Exposure to sexism at multiple levels is associated with more chronic conditions, worse self-rated health, and worse physical functioning for women.[3] A supportive workplace environment for physicians who are women is critical for women's health equity, in part because clinicians who are women are more likely to provide health care to women.[5] Despite the inclusion of women in medicine for over a generation, gender equity has been slow to materialize. Nearly half of women medical students report experiences of sexual harassment during medical school, rates substantially higher than in other STEMM graduate programs.[6] Progress in the rate of advancement of women into higher levels of faculty rank, department chairs, and cancer center directors has been limited.[7,8] Physicians who are women start with lower salaries than their counterparts who are men, and the gender wage gap continues to widen even when adjusted for factors such as rank and experience.[9,10] Differences in the work environment, leadership opportunities, and the accumulation of wealth are associated with decreased career satisfaction and higher rates of burnout for women oncologists.[11,12]

Structural sexism cannot be addressed without consideration of other forms of structural systems of discrimination and inequity that also affect patients with cancer and oncologists. Intersectionality is a framework for understanding how multiple socially constructed identity categories (ie, race, ethnicity, and gender) overlap and interact at the individual and institutional level to create disparate outcomes for

Author affiliations and support information (if applicable) appear at the end of this article.

PRACTICAL APPLICATIONS

- Structural sexism, the unequal distribution of resources and power, remains a challenge in oncology and negatively affects both physicians and patients.
- Structural sexism results in the deprioritization of specialties predominately populated by women physicians and patients and stalled progress in cancers affecting women.
- Policy and institutional solutions are needed to combat structural sexism and improve cancer care for all.

individuals and communities.[13] Structural sexism amplifies other institutional barriers such as structural racism, ableism, heterosexism, and classism, and individuals with multiple marginalized identities may be more affected by these compounding systematic forces.[14] Women who belong to groups that are under-represented in medicine face further structural challenges in addition to structural sexism; for example, Black and Latinx/Hispanic women are vastly under-represented in the specialties of medical, surgical, and radiation oncology.[15,16] This further affects patient care as diverse clinical teams are associated with increased patient satisfaction and perceived quality of care.[17,18]

Interpersonal factors that act as barriers to gender equity have been described extensively elsewhere.[19,20] To date, attempts to address the interpersonal sources of inequities have been insufficient.[21] Although implicit bias training can increase bias awareness,[22,23] reports on long-term successes of bias training are scant.[24,25] Rather than putting the onus on those affected by sexism to fix themselves, combatting structural sexism in cancer care demands the generation of specific structural solutions to foster equity related to the delivery of cancer care.

HOW CONSIDERATIONS OF SEX AND GENDER INFLUENCE CANCER CARE

Cancer incidence and outcomes are influenced by a variety of biologic, social, environmental, and economic conditions, including sex and gender.[26] The differences in cancer diagnosis and outcomes between men and women are multifactorial and poorly understood, but most likely reflect differences in both endogenous factors and exogenous factors. Both sex, as a biological variable, and gender, as a social, cultural, and structural variable, act to influence health. Historically, a 70-kg male patient was used to define

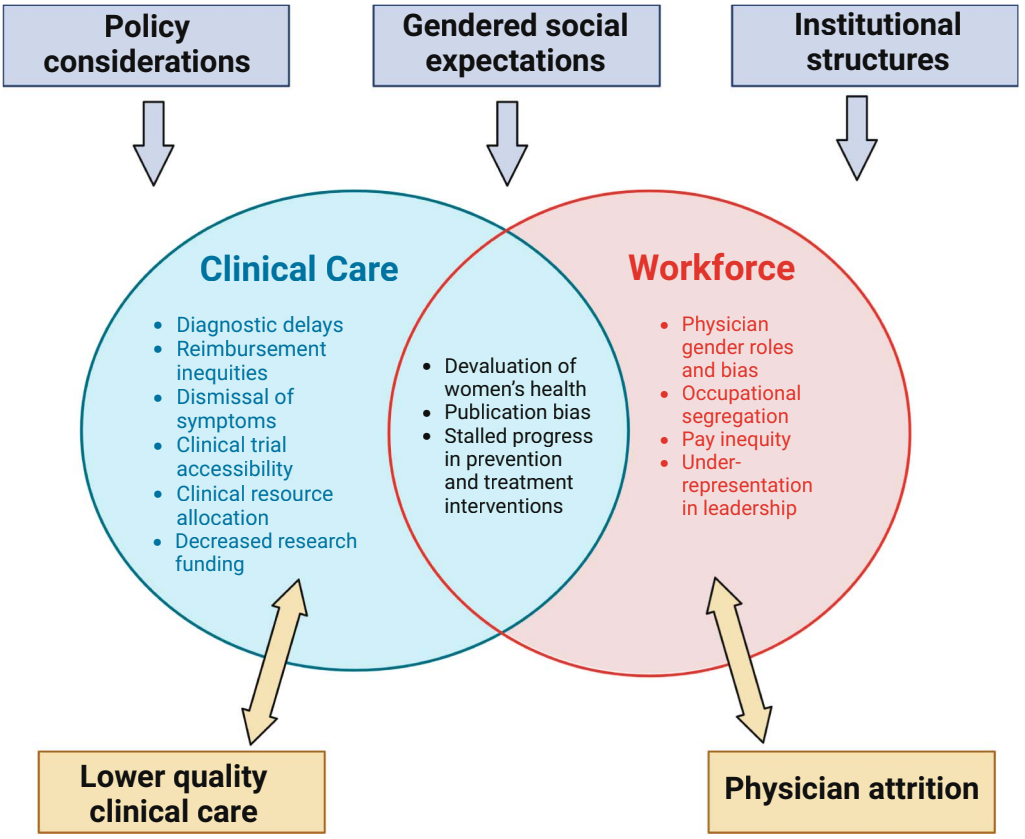

FIG 1. Structural sexism affects both oncology workforce and clinical care. Top arrows demonstrate the forces contributing to structural sexism in clinical care, physician workforce, and both domains; bidirectional arrows show the downstream outcomes which further amplify structural sexism. Created with Biorender.

the average patient in medicinal education, practice, and biomedical research.[27] Both sex and gender, therefore, influence the structure of cancer care delivery, affecting how patients receive care.

Among the components that define sex, anatomy most noticeably influences epidemiologic differences in cancer risk, treatment, and outcomes (Fig 2). Cancer incidence and mortality (male:female ratio of 1.15 and 1.37, respectively) are higher in the male US population, reflecting differences in life expectancy and sex-specific cancer disease site risk.[28] Variations in incidence and mortality by sex additionally exist across disease sites that are not sex-specific. Higher cancer risk in male patients for most cancer sites except thyroid and gallbladder persists even after adjustment for known risk factors.[28-30]

Beyond anatomy, other domains of sex exert influence across cancer biology and clinical care. Sex differences in molecular and genomic alterations have been described across cancer disease sites in specific genes, including actionable mutations, such as mismatch repair genes, and mutation signatures.[31,32] Gonadal steroid hormones alter cancer risk and outcomes, and hormonal modulation is a common component of cancer therapy.[33] Although the influence of circulating estrogen, progesterone, and androgens is primarily implicated in cancers of reproductive organs, these hormones influence tumor vasculature, stroma, and other aspects of the tumor microenvironment.[34,35] Total body water, lipid composition, and metabolism influence the pharmacodynamics and pharmacokinetics of chemotherapy agents, potentially altering efficacy and adverse events.[36,37] Differences in the male and female innate and adaptive immune responses have been well-established.[38] Distinct sex-specific immune features across multiple cancer types and differences in response and adverse events with immuno-oncology treatments have been demonstrated.[33,37,39,40] The reduction of risk of death was twice as large for male patients compared with female patients according to a meta-analysis that pooled results from 20 randomized trials of immune checkpoint inhibitors.[40]

The multiple dimensions of gender similarly influence cancer care and affect patients with cancer. Gender identity and a sense of femininity link postmastectomy breast reconstruction to an improved quality of life.[41] Cultural expectations about behavior as they are associated with certain sex traits influence cancer risk behaviors (eg, indoor tanning, cigarette smoking, and physical inactivity). Conformation to gender norms of masculinity or femininity related to these behaviors contributes to cancer incidence

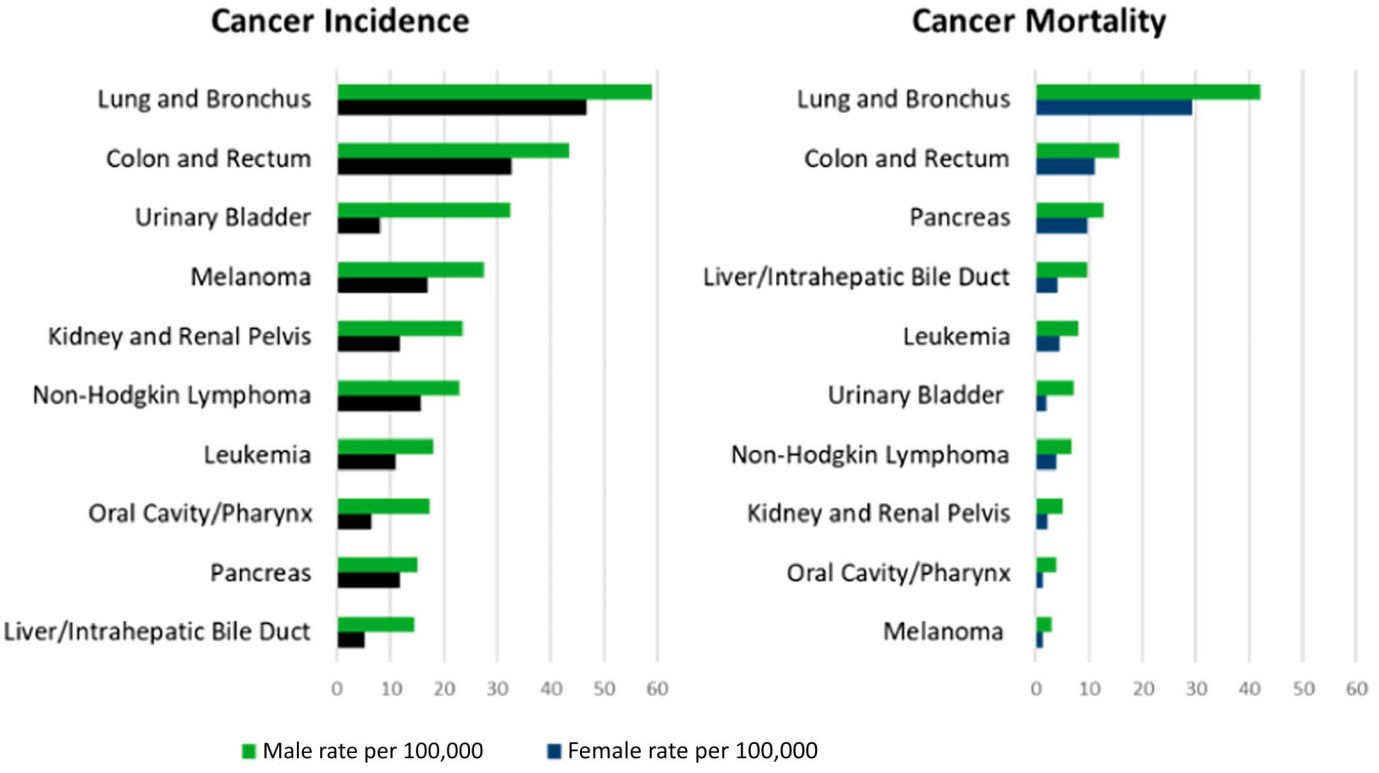

FIG 2. Age-adjusted cancer incidence and mortality rates in the United States including the years 2016-2020. Bars represent incidence and mortality rates for 100,000 male patients (green) or 100,000 female patients (blue) for the indicated cancer type. Created by SEER*Explorer.

differences between men and women.[42] Gendered assumptions that women are emotional, sensitive, and even hysterical affect the way that physical pain symptoms are interpreted by health care professionals.[43] Gender bias in the patient encounters within the health care system can lead to diagnostic delays and is significantly associated with longer diagnostics intervals in six of 11 non–sex-specific disease sites (bladder, colorectal, gastric, head and neck, lung, and lymphoma) without comparable diagnostic delays for men in any of those disease sites.[44] Repeated exposures to gender-based inequities at the individual, relational, and institutional levels accumulate and are associated with a diagnosis of chronic conditions and worse overall health.[3] The presence of comorbidities and decreased performance status are well-known factors which are negatively associated with cancer outcomes.

Access to cancer care and the patient experience differ for women compared with men. Women are more likely to have health insurance than men but less willing to incur out-of-pocket costs influencing their availability and choices in therapies.[45] Financial toxicity perpetuates health disparities in access and quality cancer treatment.[46] Although women with cancer are more likely to have a caregiver than men, caregivers to male patients are more likely to be a spouse, whereas caregivers to female patients are more likely to be a child.[47] Psychosocial support from the health care team is valued more by women than men.[48]

Gender additionally influences how we think about sex and sex-specific conditions and disorders. Stigma contributes to nonadherence with breast and cervical cancer screening for persons from sexual and gender minority communities.[49] Dismissal of symptoms of postmenopausal bleeding by health care professionals is commonly reported by women ultimately diagnosed with endometrial cancer.[50] Ovarian cancer has been historically labeled a silent killer, although nearly three fourths of patients have documented symptoms in the year before their diagnosis.[51] The care of gynecologic cancers has historically been siloed from the care of other disease sites, leaving significant infrastructure barriers to care for patients with these malignancies.[52,53]

Sex and gender may act independently of each other and in ways that can complement, enhance, diminish, or negate the other's influence on cancer risk, treatment, and outcomes.[54] Similarly, sex and gender may interact with other social factors, such as race, ethnicity, socioeconomic status, and educational attainment to affect cancer outcomes.[55] The influence of structural determinants of health, including health insurance status, geographic distance from specialty care, and transportation barriers, generally disadvantage patients with cancer from under-represented and underserved communities.[3] Presumably resulting from the intersection of multiple social and structural factors, cervical and endometrial cancer, two female-specific disease sites, have among the largest racial disparities for Black women of solid tumor types.[56] Patients with gender nonconforming identities have been shown to have lower rates of cancer screening and increased cancer mortality.[57,58]

Within the scientific literature and health policy domains, sex and gender are often used imprecisely in language and/or conflated. A recent analysis of oncology trials between 2012 and 2019 used to support FDA drug approval demonstrated that sex and gender terminologies were used inconsistently in 76% of reporting of results. None of the 128 evaluated studies described how sex and gender information was collected or assessed. Although 89% of survival data for non–sex-specific cancer sites was disaggregated by sex, no study presented disaggregated toxicity data by sex or gender.[59] Without disaggregation by sex and gender of research data, an analysis and understanding of how sex differences and gender inequalities affect health is not possible. Inattention to sex and gender in research, imprecision in language and reporting, and inadequate enforcement of journal and funder policies reflect a larger system of gender inequity that devalues women's bodies, health, and experiences.

Gender inequity is also reflected in disparities in National Institutes of Health (NIH) funding for diseases that affect women. For many diseases that affect primarily one sex, the funding pattern favors those that primarily affect men. With respect to burden of the disease within the population, female-dominant diseases are statistically more likely to be underfunded compared with male-dominant diseases.[60,61] Although there is an association between burden of disease and NIH funding, historic funding for a condition or disease is the factor most strongly associated with continued funding, thereby perpetuating male bias in biomedical research.[62] Disproportionately low NIH funding to gynecologic cancers compared with other cancer disease sites has been described.[60,63,64] Over time, persistent disparities in funding and research resources can lead to gaps in the evidence base for screening, diagnosis, and treatment of female-specific cancers, as well as limiting the pipeline of researchers invested identifying novel therapeutics for those diseases.

Reproducibility and generalizability of cancer clinical trials depend on the enrollment of populations representative of the population for which interventions are intended. Historically, exclusion of women from clinical trials rested on the gendered construction of a normal study participant as a 70-kg male patient, concerns that the normal hormonal fluctuations of the menstrual cycles might interfere with study results, and fears that enrollment of subjects capable of pregnancy might potentially lead to a teratogenic fetal exposure. The requirement that NIH-funded researchers

enroll racial and ethnic minorities and women, including women of childbearing age, into clinical research trials was codified into Federal law in the NIH Revitalization Act of 1993.[65] Although women make up approximately half of participants in NIH-sponsored research today, disparities in cancer clinical trial enrollment persist. For non–sex-specific trials completed between 2003 and 2016, female patients were underenrolled. Female enrollment to lung and pancreatic cancer trials was under 10% during this time frame while they represent over 40% of the new diagnoses.[66]

Oncology drug development depends on phase I trials made up of small cohorts of patients receiving escalating doses. In a recent analysis of National Cancer Institute (NCI)–supported phase I trials (between 2000 and 2019), similar numbers of male and female participants were enrolled and outcomes, including survival and adverse events, were similar between men and women. However, there are multiple selection biases in clinical trials enrollment that favor male participation in all phases of drug development.[67] Women are more likely than men to have multiple chronic conditions[68]; hemoglobin levels are generally lower in women, which could potentially preclude women from participation[69]; and financial toxicity related to clinical trials enrollment may disproportionately affect women's accrual.[70] Without representative populations of women participating in clinical research, the applicability of doses and efficacy of anticancer agents to the broader population of women may result in over- or undertreatment as well as excess treatment-related toxicity.

Few peer-reviewed journals are centered around the health needs of women. Publications in women's health journals remain primarily focused on reproductive health with an emphasis on obstetrics.[71] Within the broader publication community, women's health research has been shown to be less publishable—and when published, less impactful—than research focused on men.[72] Research focused on cancer care for women is also more often performed by women than men adding to other publication biases.

THE IMPACT OF STRUCTURAL SEXISM ON THE ONCOLOGY WORKFORCE

Just as the intersection of gender, power, and status affects patient care, structural sexism has wide-ranging effects on the oncology workforce. The physician identity was created by men as medicine was historically a profession performed by men.[73] The culture of medicine today reflects this history with value assigned to typically masculine traits and characteristics such as authority, objectivity, and rationality. More characteristically feminine behaviors such as acts of compassion or bidirectional communication are infrequently built into health care systems, incentivized, or rewarded.[73] The consideration of sex and gender as a binary has resulted in unique challenges, such as emotional distress, harassment, and fear, for physicians with nonconforming gender identities.[74,75] In 2021, 35.2% of practicing oncologists identified as women.[19] Yet despite large numbers of women practicing in oncology-focused specialties, women in oncology face many of the same challenges encountered by women in the larger medical community.

Gender bias or assumptions about roles, behaviors, and interactions on the basis of presumed sex are pervasive in society and medicine. Gender-biased beliefs are equally held by men and women,[76] health care professionals, and the general public.[77] Resulting from these wider societal expectations, women practicing medicine juggle a disproportionate share of household management and childcare tasks compared with their male colleagues in addition to their work as physicians.[78] Occupational gender bias, including the association of men as physicians, is identified early in childhood.[79] Gender segregation in medicine occurs at the specialty level with women tending to choose communal specialties that involve the care of women and children.[23] The specialties with the largest representation of women in the oncology workforce reflect this gendered specialty divide as 54% of gynecologic oncologists and 69% of breast surgeons are women.[80-82]

The culture of medicine—a hierarchical power structure, history of male dominance, long hours, and ample access to private spaces—makes gender-based harassment in medicine more pervasive than in other science or professional fields.[6] While explicit discrimination and sexual harassment are declining, implicit gender bias remains prevalent and can have equivalently detrimental effects over time compared with explicit discrimination.[6,83] In a recent survey of ASCO members, 70% reported having experienced sexual harassment in the past year. These experiences were more common in women compared with men (80% *v* 56%) and included gender harassment, unwanted sexual attention, and sexual coercion.[84] Inclusion of women into a specialty does not necessarily lead to decreasing rates of gender harassment. Within general surgery residencies, increasing percentages of women correlates with higher rates of gender discrimination and sexual harassment.[85] Most gynecologic oncologists (64%) report workplace gender discrimination.[86] Behaviors of these volumes, reported from such a variety of sources that include authority figures, patients, staff, and other hospital employees, suggest social forces beyond the individual level that drive gender-based harassment.[87,88]

Role congruity theory when applied to gender and medicine proposes that women will be positively evaluated when they are perceived as feminine (not a physician); however, being perceived as a woman often leads to being unrecognized as

an expert. This double bind leaves women challenged as to whether they should prioritize likeability or recognition for their expertise.[81,89] Biases held by patients and coworkers lead to the frequent misidentification of physicians who are women as nurses, support staff, or other nonphysician health care professionals leaving women to choose between laughing it off or asserting their role.[90,91] Women are less likely than men to be introduced using professional titles in a variety of setting including while speaking at grand rounds[92] and when receiving messages from patients communicating through the electronic medical record.[93] Despite representing 35.6% of physician membership within oncology professional societies, women were found to receive only 24% of the physician awards suggesting exceptional performance may be less likely to be recognized or rewarded in women.[94] Each of these seeming small undermining acts, behaviors, or dismissals accumulate, create additional work for women who are physicians to justify their skill and proficiency, and contribute to the leadership gap in medicine.[95-97]

Leadership in oncology remains disproportionately male. Over half of women practicing oncology perceive their gender to adversely affect their job promotion.[98] Within academic medical departments in gynecology and radiation oncology, a disproportionately low number of women hold the rank of full professor or department chair.[99-101] Within radiation oncology, there remains an under-representation of women in chair positions despite higher levels of grant funding for women.[102] At NCI-designated cancer centers, cancer center leadership teams are made up of predominantly White men, with women holding only 16% of cancer center director positions.[8,100,103] Women remain underrepresented in the currency of academics—women are less likely than men to publish in the senior author position, less likely to be included in authorship of clinical trials, and less likely to hold editorial positions in oncology journals.[104,105] These and other opportunities and activities can be thought of as markers of influence.[106] They coalesce and synergize to define leadership in oncology, and if, for each marker, women are less likely to be considered or awarded, stereotypes about women being less fit for leadership are perpetuated.

Gender pay gaps, arguably the most objective and transparent representation of differing value assigned to work performed by women, persist in all fields of oncology.[80,107,108] Across professions, the separation of jobs as performed primarily by women or men, or occupational segregation, explains much of the gender wage gap.[109] Men and women earn less in professions predominated by women compared with those where men are in the majority. The declines typically occur after the entry of women into previously male-dominant occupations signifying a devaluing of the same work when performed by women.[110,111] This trend has been demonstrated in medical fields including endocrinology, surgery, and gynecology.[81,110,112]

Numerous other gender-related factors explain observed differences in salary. Our current approach to physician compensation approach devalues an approach to practice favored by women (whether due to patient and coworker expectations or gender identity as a woman)—engagement in more patient-centered care and longer visits.[113,114] Female-specific procedures reimburse on average 28% lower than the comparable procedure in a male patient, a so-called double discrimination for women physicians who primarily care for breast or gynecologic malignancies.[114,115] Compensation in specialty care is most often dependent on new patient referrals. Although doctors are more likely to refer to specialists of the same gender, a bias toward referrals to men persists even with increasing representation of women within a specialty.[116,117] Patient complications lead to sharp drops in referrals to specialists who are women (and all women physicians) but not to men.[118] Women are more likely to be referred patients with complex psychosocial problems who require more time in the office and are less likely to generate procedural revenue.[11] In aggregate, women are doing more work for each work unit assigned compared with men.

SURMOUNTING THE CHALLENGE OF STRUCTURAL SEXISM IN CANCER CARE

The multiple domains of gender amplify one another leading to many barriers for patients with cancer and the oncology workforce. The downstream effects of structural sexism negatively influence the quality of care and innovation in research and are evidenced by persistent disparities in outcomes for patients with cancer and the continued barriers to career satisfaction and advancement for all oncologists, who identify as women—including cisgender, transgender, and gender diverse women—despite several decades of inclusion. Women with additional underrepresented identities are further disadvantaged by the intersection of structural sexism with other structural factors that influence health.

To overcome the challenges related to structural sexism, organizational and structural changes are required. Several cancer research and care organizations, such as European Society for Medical Oncology and ASCO, have put forth leadership development initiatives for oncologists of all backgrounds, advocated for policies advancing health equity for patients with cancer, and put forth best practices for caring for gender minority patients with cancer.[15,26,119,120] The following solutions are put forward toward creating a more equitable work and supportive clinical environment for the betterment of oncologists and patients with cancer.

- Individual oncologists should examine their own motivations, biases, and practices related to the delivery of equitable medical care to all patients.
  - Interventions to best implement and reward empathetic, trauma-informed (inclusive of recognizing and responding to the effects of traumatic stress and promoting patient safety, empowerment, and healing), and person-centered care are urgently needed across oncology care delivery environments.
- Incorporate sex and gender education in medical school, postgraduate oncology training, and continuing medical education such that the concepts are well understood by clinicians and the oncology workforce.
- Interrogate and disaggregate data from quality improvement projects by patient and health care professional gender to identify areas in need of improvement.
- Ensure inclusion of sex and gender considerations, diverse populations of researchers (including women), and patients throughout the research continuum—from hypothesis generation to study design, analysis, interpretation, and dissemination of results.
- Encourage the use of precise and accurate terminology about sex and gender in interpersonal communication, patient charts, reporting of research results, and health education related to cancer.
  - Avoid use of stigmatizing language (eg, hysterical, aggressive, and bossy) when discussing patients and colleagues and opt for gender-neutral terms when possible (eg, upset, assertive, and goal-directed).
- Enhance flexibility. Alternate schedules, job sharing, and family-friendly policies allow patients and health care professionals with any gender to better integrate cancer care with other responsibilities and ensure continuity of care.
- Enact term limits for leadership positions within organizations, professional societies, and journals. Term limits spur succession planning and innovation.
- Create cultures of inclusion and excellence, through ensuring transparent and fair metrics for patient care, administrative tasks, and research.
- Ensure transparent and fair metrics for recruitment, retention, promotion, and salary.

Equity is important to everyone, and diversity improves health care and research outcomes. Dismantling structural sexism is one piece of improving care delivery in cancer care, and the cancer research enterprise can benefit individuals of all genders and improves the health of communities of people affected by cancer.

SARCOMA

Local Therapies for Metastatic Sarcoma: Why, When, and How?

Nadia Hindi, MD[1,2]; Nadia Laack, MD[3]; Kelvin Hong, MD[4]; and Peter Hohenberger, MD[5]

overview

Management of patients with advanced sarcoma has been evolving in recent decades, from a one-fit-all perspective to a more refined, personalized, and multidisciplinary approach. In parallel, the evolution of local therapies (radiotherapy, surgical and interventional radiology techniques) has contributed to the improvement of survival of patients with advanced sarcoma. In this article, we review the evidence regarding local treatments in advanced sarcoma, as well as its integration with systemic therapies, to provide the reader a wider and deeper perspective on the management of patients with metastatic sarcoma.

Author affiliations and support information (if applicable) appear at the end of this article.

Accepted on May 13, 2023 and published at ascopubs.org on June 29, 2023: DOI https://doi.org/10.1200/EDBK_390554

INTRODUCTION

Soft-tissue sarcomas (STSs) describe a heterogeneous group of soft-tissue tumors with the WHO Handbook separating more than 60 subtypes. Being diagnosed at an early stage and achieving a complete (R0) resection of the primary tumor, the patients' prognosis might be excellent. However, metastatic tumor spread is common and may affect all parts of the body with the lungs as the predominant location[1] (Figure 1). Improved insight into tumor biology of sarcomas has resulted in significantly improved prognosis of patients over the past decade.[2]

THE CONCEPT OF OLIGOMETASTASES AND ITS IMPACT ON CLINICAL DECISION MAKING

If metastatic sarcoma presents with multiple bilateral lung metastases, systemic treatment is the treatment of choice. However, a considerable proportion of patients might have disseminated cancer with a limited number of metastases—each *per se* accessible to local treatment. For a wide spectrum of cancerous diseases including sarcoma, such an approach offers long-term survival by local treatment.[2,3] This subset of patients were called oligometastatic by Hellman and Weichselbaum in 1995.[4,5] The concept has been refined since and now also defines oligorecurrent and oligoprogressive disease.[6] The number of metastases has long been considered as one of the defining factors of oligometastatic disease (OMD), and the terms were consented to be applied by medical societies such as European Organisation for Research and Treatment of Cancer (EORTC) and ESTRO.[7] Disease characteristics and burden, time interval to the primary tumor, and other aspects were agreed on[7,8] to allow better comparison of trial results from surgery or radiation oncology for OMD. However, a systematic literature review on the completeness of reporting showed that the overwhelming publications show significant deficits.[9] A decade ago, miRNA clusters were in the focus of translational research of OMD.[10] Nowadays, the immune environment or epigenetic changes are at the forefront of research.[3,11-13]

Stereotactic radiotherapy, thermal ablation, surgical resection and refined systemic treatment options contribute to long-term survival of patients with metastatic STS. These highly selective procedures should only be administered after decision making in a multidisciplinary sarcoma board.

RADIATION THERAPY IN METASTATIC SARCOMA: MODALITIES, INNOVATION, AND CONSIDERATIONS ACROSS THE AGES

Historically, local control with conventional radiation for gross disease in sarcomas is quite poor, with limited available reports suggesting only 20%-30% local control at 2-5 years. Because of the relative radioresistance and chemoinsensitivity of sarcomas, patients with limited metastatic disease and otherwise expected longer-term survival are generally referred for consideration of surgery if metastases-directed local therapy is being considered. Prospective, randomized data for observation versus lung metastasectomy are unlikely to be obtained, but numerous series demonstrate a consistent 20% 5-year survival for patients with metastatic sarcoma to lung who are able to undergo surgical resection. Although there is almost certainly a selection bias in these series, surgical metastasectomy is generally an accepted practice for patients with OMD, especially if the lung is the only site of disease.

In contrast, pediatric sarcomas, such as Ewing, rhabdomyosarcoma, and synovial, tend to be chemosensitive and sensitive to moderate doses of radiation. For more than 20 years, it has been a standard

PRACTICAL APPLICATIONS

- Patients with advanced sarcoma could benefit from local therapies, and the multidisciplinary management of metastatic patients has probably played a role in the improvement of outcome in this population.
- Surgical resection of metastasis can provide selected patients prolonged disease control. In this article, the indications for metastasectomy are reviewed.
- New radiotherapy techniques such as stereotactic body radiotherapy are able to achieve local disease control in selected patients with metastatic sarcoma and can be an alternative to metastasectomy in patients not suitable for surgery.
- Systemic drugs combined with radiotherapy seek to increase the efficacy of radiation. Existing preclinical and clinical data on the combination of trabectedin plus palliative radiotherapy (30 Gy in 10 fractions) showed synergy and very interesting data in terms of overall response rate and outcome.

practice to attempt to consolidate patients with newly diagnosed pediatric sarcoma with comprehensive metastatic-directed therapy when feasible. Retrospective analysis of prospective pediatric studies and single-institution retrospective reviews consistently demonstrate a 20% survival in patients with metastatic pediatric sarcomas.[14-16] A closer review of the data reveals that survival generally improves to closer to 30%-40% for patients who received comprehensive metastatic-directed therapy, whereas in patients who did not receive comprehensive therapy, survival ranges from 0% to 10%.

In an attempt to improve the feasibility of metastatic-directed therapy in pediatric patients with newly diagnosed Ewing and rhabdomyosarcoma, stereotactic body radiotherapy (SBRT) and hypofractionated (higher dose over fewer days) radiation regimens was introduced into prospective COG study AEWS1221. 40 Gy in five fractions was recommended for bone metastases up to 5 cm in size. Alternative schedules were also allowed if 40 Gy in five fractions was not considered feasible secondary to toxicity concerns of nearby organs at risk (OAR). Although the primary end point, impact of insulin growth factor 1 inhibition, was negative, the OS for patients on AEWS1221, a study which limited to patients with metastatic Ewing sarcoma, was 36%. Analysis of impact of SBRT on metastatic site-directed therapy is ongoing.

A similar philosophy was adopted for patients with rhabdomyosarcoma on ARST1431. Prescription dose for this tumor, felt to be more radiosensitive, was 35 Gy in five fractions, with alternative fractionation schedules allowed. Although analysis is still ongoing, the recommended schedule has been continued on the currently open rhabdomyosarcoma study ARST2031. In the recently completed nonrhabdomyosarcoma adult and pediatric joint protocol evaluating pazopanib in addition to radiation and surgery for sarcomas, COG-NRG ARST1321, metastatic site-directed therapy was advised for all metastatic sites with either surgery or radiation. Radiation dose and fractionation was left to the discretion of the investigators. In the currently open osteosarcoma study AOST2031, patients with newly diagnosed metastatic osteosarcoma are recommended to receive comprehensive metastatic site-directed therapy as part of protocol therapy. Although it is expected that most patients will receive surgical metastatectomy, 50 Gy in five fractions is being recommended for metastatic sites including lung that are not amenable to surgical resection. Outcomes for SBRT in pediatric sarcomas have been reported in single-institutional series and a multi-institutional pilot study, and the safety and efficacy for pediatric patients receiving SBRT are demonstrated in the relapsed setting.[17,18] Local control was excellent for patients with Ewing and rhabdomyosarcoma. Osteosarcoma local control was slightly inferior suggesting that higher doses are necessary for durable local control in that disease.

With improvement in radiotherapy techniques such as SBRT that allow high-dose radiation to be delivered safely, radiation has been reintroducing as a potential modality for metastatic-directed therapy in adult sarcomas. Although for the most part patients are directed to surgery when feasible, for patients in whom surgical resection would be morbid or who are not otherwise surgical candidates, SBRT has been used to provide durable local control. Studies of lung, spine, and brain radiosurgery all demonstrate 85%-98% local control at 1-5 years, with many patients in the series experiencing prolonged survival.[19,20] Improved local control is associated with higher radiation doses, such that doses should exceed 100 Gy BED for the goal of ablative therapy.

For patients in whom ablative doses are not possible, generally because of toxicity concerns of adjacent OAR, attempts to achieve the highest dose possible are still justified as conventional palliative doses have very limited efficacy in sarcomas. Combination therapy with surgery and/or interventional radiology procedures can be considered as well for patients with good performance status or limited therapeutic options.

SBRT and modern IMRT for metastases in these populations have been very well tolerated. Pain flare can be seen with ablative doses of radiation, attributed to rapid

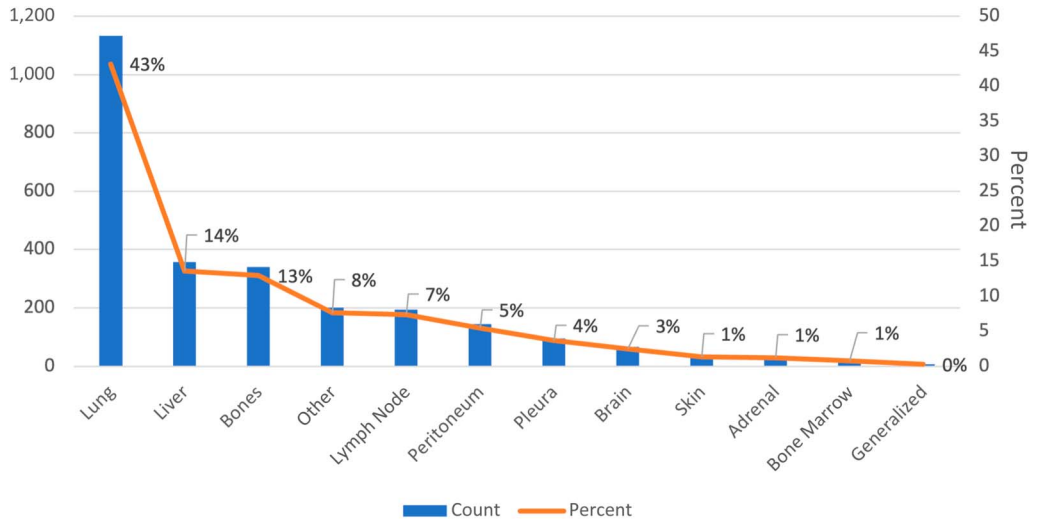

FIG 1. Frequency distribution and percentage of localizations of primary metastases (without gastrointestinal stromal tumor, N = 2,625).

tumor lysis. Treatment or pretreatment with short-course steroids can mitigate pain flares with SBRT. Radiation pneumonitis is rare but associated with ultracentral tumors, very large tumors, or multiple courses of treatment. Bone insufficiency fractures are a risk after all forms of radiotherapy but maybe a higher risk after ablative doses. Most studied are vertebral compression fractures which can occur in as high as 30% of patients as soon as 1 month after RT but can also be a late complication. For patients with features that are high risk for subsequent fracture, early intervention with vertebroplasty, with or without cryoablation if necessary to make room for safe cement placement, is recommended within 3 months of radiation. Other toxicities are generally mild and reversible (radiation dermatitis, fatigue).

Although the results of SBRT and hypofractionated ablative dose RT are encouraging, we await the results of the multiple prospective pediatric studies for both local control and acute and long-term toxicities. Although data are more limited in adult sarcomas, preliminary data more commonly in the relapsed setting suggest that high-dose SBRT provides durable local control and is an alternative to surgical metastasectomy for patients in whom surgical resection is not possible. Prospective studies in adults with newly diagnosed sarcomas are needed to evaluate the benefit of early, aggressive metastatic site-directed therapy similar to the current standard in pediatric sarcomas, to determine the safety and efficacy of this approach.

THE ROLE OF SURGICAL THERAPY FOR STS METASTASES

The recommendation to resect sarcoma metastases is often difficult because no results from randomized studies are available. The decision might depend on the subjective assessment and experience of the treating surgeon regarding extent and radicality of the intervention. In the case of surgery for recurrent metastases or when the patient's general condition is impaired, other ablative procedures can also be considered. Therefore, the indication for surgery should be made in a multidisciplinary tumor board.

The lung is the main location of sarcoma metastases accounting for about 40%, liver and bone account for 13% each, peritoneum and lymph node metastases develop at rates of 7%, and other locations are detected at even lower rates.[21,22] Thus, most publications on surgery of sarcoma metastases address the lung. The history of pulmonary metastasectomy dates back to 1882.[23] Most of the patients with pulmonary metastases are asymptomatic, and the lesions are detected during follow-up visits. Symptoms such as hemoptysis, cough, or shortness of breath are uncommon. Pain related to pulmonary metastases is only expected through chest wall invasion or a pneumothorax because of rupture of the pleural surface covering the metastasis.

Treatment Results of Lung Surgery and Influencing Factors

Numerous case series and reviews of the literature dating back over decades address very different patient scenarios.[23] A recent systematic review included series published after 2010 with at least 25 patients after metastasectomy and could analyze eight publications with 1,004 patients. Primary tumors were leiomyosarcoma (20%), synovial sarcoma (16%), and liposarcoma (6%), whereas the group of malignant fibrous histiocytoma/undifferentiated pleomorphic sarcoma (UPS)/undetermined STS accounted for 42% of the cases[24]; an extract of the data is shown in Table 1. In median, two lung metastases were resected at one time; the recurrence rate was 34% in one series and around 80% in both others. Patients can be offered a 90% chance of complete (R0) resection combined with a low complication rate (average of 10.8% in three series

TABLE 1. Extraction of Data From Eight Publications Evaluated in a Systematic Review[24]

Variable	Average	Worst	Best	Data NA
OS (median, months)	42	33.2	79.5	—
5-year-survival rate	35%-50%	8.5%	58%	1
DFS (median, months)	20	6.8	27	2
R0 resection rate	89%	74%	97%	1
No. of metastases. resected (median)	2	1	40	1
DFI to primary tumor (median, months)	16	9	30	2
Type of surgery, % minimally invasive	24%	0	29%	0
Recurrence rate	81%	82%	79%	5
Repeat pulmonary metastasectomy	34%	42%	16%	2
Complication rate	10.8%	14.7%	9.1%	5
Mortality	1.2%	3%	0%	2

Abbreviations: DFI, disease-free interval; DFS, disease-free survival; NA, not available; OS, overall survival.

reporting data), and operative mortality in six series was very low with 1.2%. The median overall survival (OS) after surgery ranges from 33 to 79.5 months. Depending on intensity of follow-up, the disease-free interval (DFI) is around 20 months. It did not matter whether an open or a minimally invasive procedure was performed. No relevant differences in R0 rates and DFI could be observed.[23] With more refined thoracoscopic procedures and improved computed tomography (CT) staging, the surgical approach can be easily adapted to the individual patient.

Seven of eight series evaluated prognostic factors with inconsistent results. Only DFI >12 months and solitary versus multiple nodules were mentioned in 6 of 7 reports. Like in other series, potential prognostic factors include a wide range from leiomyosarcoma subtype, neutrophil count, or response to preoperative chemotherapy.[23,25]

The recently published evidence-based German guideline on STS[26] states that surgical resection of pulmonary metastases of STS is encouraged and indicated, if

1. R0 resection of all pulmonary metastases is expected.
2. There are no signs of local tumor recurrence at the site of the primary tumor that cannot be controlled locally.
3. Prior pulmonary metastasectomy is no contraindication.
4. The patients' quality of life should play an important role in the decision making and, less invasive and better tolerable procedures should be preferred.
5. In metachronously resected lung metastases, there is no indication for additive chemotherapy.
6. Resection of pulmonary metastases with palliative intent is not recommended and should be reserved for exceptional cases with severe symptoms.
7. In case of the presence of extrapulmonary metastases, surgical removal of pulmonary metastases must be an interdisciplinary decision in an individual case.

Magnitude of the Effect of Surgery Versus Nonsurgical Management and Chance of Long-Term Survival

A propensity-matched comparison of 1,578 patients treated from 1998 to 2015 with metachronous metastases from extremity and trunk STS tried to quantify the effect of metastasectomy on OS.[27] Patients from two European centers had myxofibrosarcoma in 29%, synovial sarcoma in 13%, and UPS in 10% as the most common histological subtypes. OS was significantly longer in 68 patients undergoing metastasectomy than in 67 patients who did not (10-year OS, 23% *v* 4%; hazard ratio [HR], 0.34; 95% CI, 0.22 to 0.53; $P < .0001$). The effect prevailed after weighting of the data to control for the higher prevalence of favorable prognostic factors in the surgery group (adjusted 10-year OS, 17% *v* 3%; log-rank $P < .0001$; HR, 0.33; 95% CI, 0.20 to 0.52; $P < .0001$). Five-year OS was 27.8% in patients who had and 14.5% in patients who had not undergone metastasectomy within the first 3 months after diagnosis of a metastasis ($P < .0001$).

The potential benefit of surgical intervention was consistent across important clinical subgroups such as Eastern Cooperative Oncology Group status, metachronous interval more or less than 12 months, or age younger or older than 70 years at metastasis diagnosis. However, the benefit of metastasectomy was stronger in patients with a single metastasis (HR, 0.21) than in patients with multiple metastases (HR, 0.44). The results are more encouraging than those published a decade ago with a 5-year OS of 17%.[28]

A multistate modeling of 443 patients integrated multiple risk factors as local recurrence, metastases, and clinical end points into a single statistical model to avoid that the Kaplan-Meier method may overestimate actual long-term survival. With a median follow-up of 6 years, 84%, 52%, and 23% of patients had being followed for more than 1, 5, and 10

years, respectively. The 15-year cumulative incidences of local recurrence, distant metastasis, and death from any cause, using a competing risk analysis, were 16% (95% CI, 11 to 22), 21% (95% CI, 17 to 26), and 55% (95% CI, 44 to 67), respectively.[29] Patients who experienced a local recurrence were more likely to develop distant metastasis (HR, 8.4; 95% CI, 4.3 to 16.5; $P < .001$) and to die (HR, 3.4; 95% CI, 2.1 to 5.6; $P < .001$). The occurrence of distant metastasis was associated with a strong increase in the risk of death (HR, 12.6; 95% CI, 8.7 to 18.3; $P < .001$). Distant metastasis occurring after a long DFI was not associated with a more favorable prognosis with respect to mortality. The relative decrease in the adverse effect on mortality for 1-year delay of distant metastasis is 0.9 (95% CI, 0.7 to 1.1; $P = .28$).

Aggressivity of surgical treatment is a significant contributor of long-term survival. A group of 97 patients treated for stage III STS could be split into 61 patients (62.9%) who survived for more than 5 years followed up with a median of 7.3 years (range, 5.0-17.3 years). The median survival of the 36 short-term survivors was 1.3 years (range, 0.3-3.3 years), and these patients underwent less aggressive treatment against recurrence, particularly less surgical resection of metastatic disease.[30]

The more the scenario of OMD is fulfilled (no history of polymetastatic disease) the earlier the indication for surgical therapy is on safe ground. Pulmonary has the potential to result in long-term survival[2,23]

Surgical Treatment of Nonpulmonary Metastases

All sites of the body can be targets of metastases from sarcoma, for example leiomyosarcoma tend to show a higher rate of metastases to the liver and soft tissues.[31] Metastases to the skeleton are more often detected in myxoid-round cell and dedifferentiated liposarcoma.[32] Data on resection of sarcoma metastases at such sites are scarce. The likelihood of nonpulmonary metastasis (NPM) occurring in the absence of lung metastasis is low and affects roughly 10% of all patients developing metastases. Malignant periferal nerve sheath tumor, angiosarcoma, rhabdomyosarcoma, synovial sarcoma, and myxoid liposarcoma were six times more likely to develop initial NPM than other subtypes of STS with an odds ratio of 6 (95% CI, 1.93 to 18.65; $P < .01$[33]). For resection of liver metastases, a systematic review summarizes six studies on 212 patients dating back to 1982.[34] The largest series with 128 patients resected for non-GIST liver metastases (49% leiomyosarcoma) in 1998-2015 reports 5-year OS rate of 49.3% and RFS of 14.9% with no difference in OS or RFS between histological subtypes.[35]

Brain metastases from sarcoma are a rare event but can develop in all subtypes including GIST. In alveolar soft part sarcoma, they are often detected at initial diagnosis. A systematic review analyzed 10 studies published from 1994 to 2020 on the treatment of brain metastases of STS, and 269 patients underwent metastasectomy. With a follow-up between 14 and 29 months, the median OS ranged from 7 to 25 months.[36] Similar to the view of neurosurgeons, resection may be a realistic treatment option in patients with up to three metastases and is particularly indicated in symptomatic lesions.[37] A randomized controlled trial of preoperative versus postoperative stereotactic radiosurgery for surgically resectable brain metastases is ongoing (ClinicalTrials.gov identifier: NCT04474925).

Regarding lymph node metastases, the overall incidence is reported to be 4.2%.[38] Clear cell sarcoma (16%), epithelioid sarcoma (13%), angiosarcoma (6.1%), and synovial sarcoma (3.8%) are subtypes with the highest incidences.[38,39] It is important to consider which age cohorts are being studied.[40] Prognostically, it was reported that surgical resection of isolated lymph node metastases results in better OS than resection of pulmonary metastases[41,42]

In summary, the recommendation for surgery in NPM should only be done following an interdisciplinary discussion, if an R0 removal of all metastases can be performed and in the abscense of uncontrolled local recurrence. Resection of liver metastases with palliative intent is not recommended. Metastases from other sites may be surgically removed on a case-by-case basis and after multidisciplinary tumor board discussion.[26]

Communication Skills

In the discussion with the patient one should avoid the palliative (systemic treatment) versus curative (surgery) perspective. Surgical removal of metastases should render the patient free from disease postoperatively. This might turn out that it did cure the patient. More realistically it offers the opportunity for long-term disease control—until the detection of a (hopefully late) recurrence.[43] This strategy opens the door for a shared decision making on the basis of realistic assumptions. A French study of patients with metastatic sarcoma demonstrated that 39 of 436 patients (9%) were still alive 5 years after diagnosis of metastases with a median survival of 12 years.[2]

Future Aspects

Two emerging factors might positively influence the contribution of surgical treatment in the future: control of the surgical effect on the metastatic cell load via cDNA as it is already applied for sarcoma subtypes such as GIST or Ewing sarcoma. Monitoring cDNA could provide a tool to better combine local and systemic treatments.[44-46] Technical development brings CT-guided surgery of pulmonary nodules to the hybrid operation theater. The more widespread use of nonintubated videothoracopy-assisted, uniportal lung

resection should further add to patient-tailored surgical procedures of very low morbidity.[47,48]

INCORPORATING SYSTEMIC THERAPIES WITH LOCAL MODALITIES IN METASTATIC SARCOMA

As previously stated, systemic treatment is the mainstay of therapy in patients with advanced/metastatic unresectable STS.[49] Although patients with metastatic sarcoma still have a poor prognosis, expected median OS in this population has clearly increased in the past decades, from around 12 months[50] to nearly 2 years in more recently published clinical trials.[51,52] The incorporation of several second-line options (trabectedin, pazopanib, and eribulin) to the therapeutic armamentarium has contributed to this increase in OS, but the better refinement in patients' management, with a multidisciplinary approach, even in the advanced setting, has also played a role. This multimodal view has allowed us incorporating local therapies to systemic drugs, maximizing symptom and disease control options.

When designing the first line of therapy of a patient with advanced STS, treatment objective is a relevant issue to be discussed and defined upfront to better select the proper treatment modality. In the case of patients with asymptomatic unresectable disease, systemic therapy with anthracyclines or, in selected patients, close follow-up could be the treatment of choice. However, there are patients in whom a multimodal approach can be indicated or needed. Patients with OMD at diagnosis, for example, could be candidates to a more intense first line, that is, anthracycline-based combinations, to maximize the possibility of achieving an objective response,[53] with the aim of facilitating a subsequent surgical resection. It is especially important to discuss with the patients the risk of a higher toxicity for these more intense approaches, as anthracycline combinations present significantly higher risk of grade 3-4 adverse events, especially hematologic, when compared with doxorubicin alone.

Patients with symptomatic lesions could also be candidates to local therapy of the symptomatic lesion in combination with systemic treatment. Palliative surgeries can be necessary in the context of unresectable metastatic disease, for example in the case of bleeding or ulcerated primary tumors. Despite the absence of prospective evidence, the combination of chemotherapy and definitive radiotherapy of the primary tumor may also be an option in patients with metastatic sarcoma and unresectable primary tumors (especially in symptomatic tumors). In the case of concomitant chemoradiotherapy, with anthracyclines and ifosfamide, the experience in the localized setting showed a higher risk of grade 4 thrombocytopenia, something that has to be taken into account, especially given the palliative setting.[54]

Beyond first line, several drugs are used and/or approved in the second and further lines: ifosfamide, gemcitabine combinations, trabectedin, pazopanib, eribulin, and dacarbazine. With the exception of specific drugs in specific histologic subtypes (ie, high-dose ifosfamide, which can induce responses in a high proportion of patients with synovial sarcoma,[55,56] or gemcitabine combinations, especially active in leiomyosarcoma and undifferentiated pleomorphic sarcoma[57,58]), the chances of obtaining an objective response with these drugs is lower than 10%.[59-61] This is relevant because, consequently, the chances of achieving symptomatic benefit with chemotherapy alone in those patients with symptomatic disease are scarce.

As previously discussed, radiotherapy is a useful tool in the metastatic setting for disease and symptom control. Systemic therapies, in addition to contribute to obtain systemic disease[62] control, can potentiate the effects of radiotherapy, acting as radiosensitizers. Several mechanisms have been described, by which systemic drugs can enhance the activity of radiotherapy: induction of DNA damage (ie, cisplatin induces DNA adducts, making cells more vulnerable to RT), interaction with relevant cell processes (such as angiogenesis), or modulation of cell cycle (to synchronize cells and induce cell cycle arrest in the most radiosensitive cell cycle phase [G2/M]). In sarcoma, there are scare data on systemic therapies (beyond anthracyclines and ifosfamide) and its concurrent administration with RT. Haas et al[62] tested in a small phase I study the concurrent administration of preoperative pazopanib and radiotherapy in patients with high-risk localized STS. Although no patients showed radiological responses, pathological response in >95% of the tumor volume was found in four of 10 tumors in the surgical specimens. However, this experience is difficult to extrapolate to the metastatic setting. Although the toxicity profile in the previous study was the expected for pazopanib (grade 3-4 adverse events mainly related with hepatotoxicity), there could be some concerns in the advanced disease setting in terms of toxicity. The previous study was developed in patients with tumors in limbs or trunk wall, but the main location for metastatic disease in sarcoma is lungs. Pneumothorax has been described as adverse event in a proportion of patients treated with pazopanib,[63] and, in the absence of specific studies in the metastatic setting, the concurrent use of pazopanib and radiotherapy should be taken with caution.

Trabectedin is another drug approved for the therapy of patients with pretreated advanced STS. Several mechanisms of action have been described for trabectedin: immunomodulatory effects by its interaction with tumor infiltrating macrophages, transcriptional modulation and DNA damage induction (by its ability to bind the minor grove of DNA), and interestingly, effects on cell cycle, inducing accumulation of cells in G2/M.[64] This latter confers trabectedin radiosensitizing properties, something that was already described in preclinical models a couple of decades ago.[65] The combination of trabectedin and radiotherapy in sarcoma was

explored in the TRASTS trial, a phase I/II academic study sponsored by the Spanish Group for Research in Sarcoma, with the collaboration of Italian and French Sarcoma Groups. The cohort A of this study explored the safety and efficacy of the combination of trabectedin and radiotherapy (with the regimen of 30 Gy in 10 fractions, considered a low-dose, palliative regimen) in patients with metastatic sarcoma. This study showed that this regimen is safe, being the adverse events observed those expected for trabectedin alone, with the exception of some cases of transient pneumonitis in RT fields. In terms of efficacy, the regimen showed a very interesting activity, with 60% of the patients included in the cohort achieving RECIST objective responses according to a central radiological review. In addition to this, outcome was also interesting in terms of progression-free survival (PFS), with 9.9 months for the phase II part, whereas median OS had not been reached at the time of the analysis.[66] Beyond this study, the experience in 40 patients with advanced STS treated with the same combination of study has also been published.[67] In this nonselected, real-life population, the combination of trabectedin and radiotherapy was able to induce objective responses in one third (32.5%) of the patients included in the series. The median PFS in this series exceeded 7 months, and the median OS was almost 2 years, very interesting data for a pretreated advanced STS population. The translational studies performed within TRASTS trial confirmed in sarcoma the finding of the synergy between trabectedin and RT, already observed in carcinoma cell lines. Of note, cell cycle modulation (G2/M accumulation) had its peak at 12 hours after trabectedin administration. This finding provides a potential explanation for the better results found in the TRASTS study when compared with the real-life series, in which the start of RT was delayed for more of 24 hours in up to one third of the patients. With all these data, the recommendation would be to start RT as soon as possible after the end of trabectedin cycle, to maximize the synergy between both therapeutic tools.

This regimen constitutes an attractive alternative for patients with advanced STS, especially those who need a dimensional reduction to obtain symptomatic relief. Currently, the phase II multicohort Synergias Study (ClinicalTrials.gov identifier: NCT05131386) is exploring the activity of this combination not only in STS but also in bone and small-cell sarcomas, with a special focus in quality-of-life items.

CONCLUSIONS

Treatment of patients with advanced STS is challenging, and patient survival in this setting has still a wide margin of improvement. Although outcome is still poor, globally the situation has improved in the past decades, and the median OS has almost doubled for these patients. Several circumstances could explain this improvement: First, more second-line systemic options are available. Second, the fact that the multidisciplinary management of the localized setting has been translated to patients with advanced STS, as local therapies can also be considered for these patients. Medical oncologists, together with surgeons, radiotherapy oncologists, and interventional radiologists, are responsible of designing the best management for each patient in an individual basis. The final aim of this multimodal approach should be to provide the best outcome with the best quality of life, always integrating and respecting patient preferences. Technical advances in the past decades have brought less invasive surgical procedures, refined RT techniques such as SBRT, and interventional radiology therapeutic options which, added to systemic therapies in selected patients, have enlarged the therapeutic perspectives of this population. In addition, the improvements in the knowledge on the molecular background of the different histological subtypes and the knowledge on the mechanisms of action of the several available drugs have also added a new layer in the refinement of the management of advanced disease.

SARCOMA

Bad to the Bone: Emerging Approaches to Aggressive Bone Sarcomas

Georgina E. Wood, MD, PhD[1]; Laurie A. Graves, MD[2]; Elyssa M. Rubin, MD[3]; Damon R. Reed, MD[4]; Richard F. Riedel, MD[5]; and Sandra J. Strauss, MD, PhD[1]

overview

Bone sarcomas are rare heterogeneous tumors that affect patients of all ages including children, adolescent young adults, and older adults. They include many aggressive subtypes and patient groups with poor outcomes, poor access to clinical trials, and lack of defined standard therapeutic strategies. Conventional chondrosarcoma remains a surgical disease, with no defined role for cytotoxic therapy and no approved targeted systemic therapies. Here, we discuss promising novel targets and strategies undergoing evaluation in clinical trials. Multiagent chemotherapy has greatly improved outcomes for patients with Ewing sarcoma (ES) and osteosarcoma, but management of those with high-risk or recurrent disease remains challenging and controversial. We describe the impact of international collaborative trials, such as the rEECur study, that aim to define optimal treatment strategies for those with recurrent, refractory ES, and evidence for high-dose chemotherapy with stem-cell support. We also discuss current and emerging strategies for other small round cell sarcomas, such as *CIC*-rearranged, *BCOR*-rearranged tumors, and the evaluation of emerging novel therapeutics and trial designs that may offer a new paradigm to improve survival in these aggressive tumors with notoriously bad (to the bone) outcomes.

INTRODUCTION

Primary bone sarcomas are rare heterogeneous tumors that make up <1% of cancers. They include a number of aggressive subtypes. Many groups of patients have poor outcomes, and they have seen little improvement over recent years. Increased collaboration and improved understanding of tumor biology have revealed promising therapeutic targets and contributed to defining treatment strategies. This review focuses on emerging approaches to therapy in these tumors.

Systemic Approaches Across the Spectrum of Chondrosarcoma

Chondrosarcomas (CSs) are rare mesenchymal neoplasms defined by the production of an abnormal cartilaginous matrix. They represent approximately 25% of all primary malignant bone tumors and have diverse morphological features and clinical behavior. Conventional chondrosarcoma (cCS) accounts for 85%-90% of CSs. Non-cCS variants include mesenchymal chondrosarcoma (MCS), dedifferentiated chondrosarcoma (DCS), and clear cell CS (Table 1).[1] These are a challenging group of tumors with limited standard-of-care systemic options, lack of prospective evidence for management, and poor outcomes in patients with metastatic or unresectable disease. Here, we discuss current management and emerging systemic therapies.

Current management. cCSs primarily arise in the medulla of the bone (central CS). Most CSs are solitary but are occasionally multifocal in syndromic patients with underlying multiple osteochondromas and enchondromatosis.[2] Grade 1 cCSs or atypical cartilaginous tumors have low metastatic potential,[3] whereas grade 2 and 3 cCSs are more aggressive with higher metastatic potential and reduced 10-year survival. Surgical excision is the primary treatment modality of CS. Conventional chemotherapy has very limited activity in patients with advanced cCS and is not recommended.[4]

Occasionally, cCS dedifferentiates into a high-grade aggressive sarcoma, DCS, which is associated with dismal outcomes.[3] Approximately 20% of patients with DCS present with metastatic disease, with a median overall survival (mOS) of <9 months.[5] On the basis of several studies with small patient numbers, a survival advantage for neoadjuvant or adjuvant chemotherapy in DCS has been demonstrated.[6-8] Conversely, retrospective data from the European Musculo-Skeletal Oncology Society group did not demonstrate an obviously improved survival with adjuvant chemotherapy.[9] Despite these relatively limited and conflicting data, chemotherapy is often considered for patients with DCS in the adjuvant and advanced setting, with anthracycline-based chemotherapy regimens most commonly used.[10]

MCS is a very rare distinct subtype that affects younger patients. MCS is composed of undifferentiated small

PRACTICAL APPLICATIONS

- Due to the rarity and complexity of aggressive bone sarcomas, patients should be managed in expert sarcoma centers.
- In conventional chondrosarcoma (cCS), chemotherapy is not the standard of care, but novel therapeutic targets are under evaluation, and patients should be considered for clinical trial entry where possible.
- Recent clinical trials have defined standard of care for patients with localized Ewing sarcoma (ES), but trials for patients with metastatic or recurrent ES have failed to demonstrate a significant improvement in survival.
- Retrospective analyses have provided insights into management and outcomes of other small round cell sarcomas, including *CIC*- and *BCOR*-rearranged sarcomas; however, controversies remain regarding the optimal treatment strategy for these patients.
- Multitargeted tyrosine kinase inhibitors (MTKI) have demonstrated efficacy in several bone sarcomas, including ES and osteosarcoma, and ongoing trials aim to define their place in therapy.
- The current system of identifying new agents for bone sarcomas is limited to those that exhibit responses or prolong event-free survival (EFS) in those with measurable disease, thereby not addressing resistant residual populations that lead to relapse.
- Current promising strategies focus on different mechanisms, such as targeting altered cell cycle, DNA damage repair mechanisms, surface proteins, and kinases, and improving immune responses.

round cells (SRCs) and variable amounts of well-differentiated hyaline cartilage and is characterized by the presence of a specific gene fusion between *HEY1 and NCOA2*.[11] For localized disease, surgery is the mainstay of treatment. Tumors are typically radiosensitive, and adjuvant radiotherapy is recommended particularly for large tumors.[2] This high-grade, aggressive neoplasm is typically chemosensitive. Adjuvant anthracycline-based chemotherapy is associated with a significant reduction in recurrence and death.[12] The consensus of many groups is to use Ewing sarcoma–like treatment regimens, although, to our knowledge, no randomized studies have been performed. Metastatic disease at presentation (10% of cases) is more common than in cCS[6] and is the strongest prognostic indicator.[13] There are phase II data indicating a role for trabectedin in advanced disease.[14] Other rare variants include periosteal CS and clear cell CS. These are low-grade variants with no specific systemic therapeutic options.

Targets and novel systemic treatment options in CS. There is an urgent need for new targeted therapies in CS, particularly for those with advanced and metastatic disease. Increased understanding of biology has provided the rationale for novel therapeutics, but historically clinical translation has been disappointing, including that of Hedgehog inhibitors that yielded great promise preclinically but failed to demonstrate a survival benefit in two large phase II clinical trials.[15-18] In addition, because of the rarity of the disease and heterogeneity of the natural history of CS, with relatively indolent disease observed in a proportion of patients, lack of standardization of inclusion criteria and lack of random assignment make the interpretation of benefit challenging. There are currently no targeted therapies approved for CS; however, increasing evidence and ongoing clinical trials hold promise for the future.

Pazopanib is a multitargeted tyrosine kinase inhibitor (MTKI) that has shown clinical benefit in patients with CS. Prolonged stability of disease has been seen in patients with progressive CS,[19] and phase II trial data demonstrated a median progression-free survival (mPFS) of 7.9 months (95% CI, 3.7 to 12.6).[20] However, pazopanib is not licensed for treatment of cCS, and although frequently used in the management of advanced metastatic disease in the United States, it is not currently available in many countries in Europe. The REGOBONE trial, which evaluated the MTKI regorafenib, across bone sarcomas, demonstrated encouraging results in the cCS cohort, with an improved mPFS of 19.9 weeks in the regorafenib arm compared with 8 weeks in the placebo arm; however, this small trial did not meet its primary end point.[21] There is anecdotal evidence that MTKIs may offer disease control in MCS, but data from clinical trials are lacking.[22]

IDH1 and *IDH2* mutations are the most common mutations found in CS, first described by Amary et al in 2011, in 56% of CS. These mutations are thought to be an early event in the pathogenesis of disease as they are present in enchondromas, through to cCS and DCS, and in patients with both solitary and multiple neoplasms.[23] Mutations in the *IDH1/2* genes are some of the best described genetic alterations linking oncogenesis and metabolism and hence a potential therapeutic avenue in multiple cancers, including CS. Preclinical data were encouraging, showing that drug inhibition of IHD1 (with AGI-5198) reduced the production of 2-HG by up to 90% in *IDH1/2*-mutant CS cells.[24-26] However, only a moderate decrease in viability was observed in some mutant *IDH1* cell lines and tumor models.[26] Outcomes from clinical trials have been mixed.

TABLE 1. 2020 WHO Classification and Features of Select Bone and SRC Tumors

Tumor Subtype	Clinical Features	Molecular Features
Chondrogenic tumors		
Central atypical cartilaginous tumor, grade 1 (ACT/CS1)	ACT = appendicular skeleton (long + short tubular bones) CS1 = axial skeleton (flat bones including pelvis, scapular and skull base) Primary conventional central ACT/CS1—arise centrally in bone without benign precursor Secondary conventional central ACT/CS1—arise centrally in bone in association with a preexisting enchondroma	*IDH1* or *IDH2* mutation (50% primary; 78% secondary)
Secondary peripheral atypical cartilaginous tumor, grade 1	Adults Age: 20-40 years Flat bones and appendicular skeleton	Germline *EXT1* or *EXT2* mutation
Central chondrosarcoma grade 2 and 3	Adults Third to sixth decades of life Bones of extremity or pelvis	*IDH1* or *IDH2* mutation (50%) *RB1* pathway alteration (86%) *TP53* mutation (20%-49%) *COL2A1* (45%), *YEATS2* (12.3%), *EGFR* (19%), *NRAS* (18%), *CDKN2A* (rare) mutations
Dedifferentiated chondrosarcoma	Adults Median age: 59 years (range, 15-89 years) Long bones, pelvis, and scapula	*IDH1* or *IDH2* mutation (50%-87%) *TP53* mutation (20%-49%)
Mesenchymal chondrosarcoma	Adults Second and third decades of life Bone, soft tissue, intracranial	*HEY1—NCOA2* fusion
Periosteal chondrosarcoma	Adults, peak incidence third decade of life Usually located in the metaphysis of long bones (distal femur, humerus)	*IDH1* or *IDH2* mutation
Clear cell chondrosarcoma	Adults Epiphysis of long bones (femoral and humeral head)	Diploid genome *P53* overexpression in the absence of mutation
Undifferentiated SRC sarcomas of bone and soft tissue		
Ewing sarcoma	Children to young adults, peak incidence in adolescents Bones of extremity or pelvis	*FET-ETS* fusion (*EWSR1-FLI1* 85%, *EWSR1-ERG* 10%)
CIC-rearranged sarcoma	Children and adults, peak incidence in the third decade Soft tissue of extremity, trunk, head/neck, retroperitoneum Aggressive course with poor response to chemotherapy	Fusions of *CIC-DUX4* (95%), *CIC-FOXO4*, *CIC-LEUTX*, *CIC-NUTM1*, *CIC-NUTM2A* (rare)
BCOR-rearranged sarcoma	Children, AYA, predilection in males Long or flat bones (*BCOR*-ITD, soft-tissue tumors of trunk, head/neck, retroperitoneum) Outcomes more favorable than those of *CIC*-rearranged sarcomas	Fusions of *BCOR-CCNB3* (most common), *BCOR-MAML3*, *BCOR3-ZC3H7B*, and *BCOR*-ITD
EWSR1–non-ETS sarcoma	Children and adults *EWSR1-NFATC2*: 4:1, long bones: soft tissue *FUS-NFATC2*: exclusively long bones *EWSR1-PATZ1*: soft tissue of the chest wall or abdomen	Fusions of *EWSR1-NFATC2*, *FUS-NFATC2*, *EWSR-PATZ1*

Abbreviations: AYA, adolescent young adult; ITD, internal tandem duplication; SRC, small round cell.

The phase I study of ivosidenib (ClinicalTrials.gov identifier: NCT02073994) in solid tumors with an *IDH1* mutation showed good oral exposure, a long half-life with persistent plasma 2-HG inhibition observed in *IDH1*-mutant tumors, and an acceptable toxicity profile.[27,28] In the CS cohort, there were encouraging results with a mPFS of 5.6 months (95% CI, 1.9 to 7.4).[28] The phase I/II study of IDH1 inhibitor olutasidenib (ClinicalTrials.gov identifier: NCT03684811) recruited 23 patients with CS. The phase I/II study of the US Food and Drug Administration approved IDH2 inhibitor enasidenib[29] in solid tumors including CS (ClinicalTrials.gov identifier: NCT02273739) and completed accrual in 2018. The dual inhibitor of IDH1/2, vorasidenib (ClinicalTrials.gov identifier: NCT02481154), is also under investigation in CS. The efficacy results of these trials are eagerly awaited.

Tumor necrosis factor–related apoptosis-inducing ligand (TRAIL) receptor (DR4 or DR5) agonists are promising cancer therapeutics as they selectively induce apoptosis in cancer cells. Monoclonal antibodies targeting DR5 are under development. Among them, INBRX-109 appears promising for CS with a phase I trial demonstrating favorable disease control and objective response rates and a mPFS of 7.4 months.[30] An international randomized phase II trial is ongoing.[31]

The immune microenvironment of CS remains poorly understood. Immunohistochemical analysis of CS tissue microarrays reported PD-L1 expression in around 40% of patients with DCS, with expression exclusively in dedifferentiated components of the tumors and an absence in cCS and MCS.[32] Biomarkers predictive of response, however, are lacking. The phase II SARC 028 study investigated the use of pembrolizumab in advanced bone and soft-tissue sarcoma. Among five patients with CS enrolled, one patient with DCS achieved a partial response (PR).[33] In a phase II study assessing pembrolizumab with doxorubicin in patients with advanced anthracycline-naïve sarcoma, three of eight patients with CS had a PR to therapy.[34] The phase I/II ImmunoSarc study investigating sunitinib and nivolumab in advanced bone and soft-tissue sarcoma demonstrated the initial evidence of activity in DCS; recruitment in this cohort is ongoing.[35] Further ongoing immunotherapy agent trials are detailed in Table 2.

The PI3K-AKT-mTOR pathway is highly active in CS[37,38]; however, activating mutations in the pathway are very rare.[39] Preclinical evidence has indicated the activity of inhibitors to a number of these kinases in CS.[40,41] Furthermore, a small retrospective clinical study of the mTOR inhibitor sirolimus plus cyclophosphamide in patients with unresectable CS showed disease control with preliminary results from a phase II trial of the combination also demonstrating disease stability.[42]

The second most frequent mutation in cCS and DCS occurs in the *TP53* gene (20%-50%).[43,44] Overexpression of TP53 or its alteration correlates with higher histologic tumor grade suggesting a role in tumor progression.[45] TP53 remains undruggable. Other frequently aberrated genes in CS relate to the cell cycle control process, and the retinoblastoma protein pathway, with loss of expression of cyclin-dependent kinase 2A/B (CDKN2A and CDKN2B) commonly seen in high-grade cCS.[43] These provide a rationale for patient inclusion in studies evaluating CDK4/6 inhibitors such as abemaciclib (ClinicalTrials.gov identifier: NCT04040205). Similar agents, however, have failed as monotherapy across multiple cancer types; thus, it remains undetermined whether there is utility for patients with CS.

Finally, epigenetic dysregulation may represent a potential barrier for tumor progression and target for therapeutic intervention with CS demonstrating high sensitivity to histone deacetylase (HDAC) inhibition independent of isocitrate dehydrogenase mutation status in *in vitro* models.[46] Additionally, a combination of a DNA methyltransferase inhibitor and the HDAC inhibitor, suberanilohydroxamic acid, impaired the proliferation of CS models *in vitro* and in xenograft models, leading to an ongoing combination phase II study (ClinicalTrials.gov identifier: NCT04340843).

Controversies in Managing High-Risk and Relapsed Ewing Sarcoma and Other SRC Sarcomas

Ewing sarcoma (ES) is a SRC sarcoma that is molecularly defined by the presence of a *FET* (most commonly *EWSR1*)-*ETS* fusion.[47] More broadly, the family of other undifferentiated SRC sarcomas encompasses those with *EWSR1*–non-*ETS* fusions and *BCOR* or *CIC* rearrangements (Table 1).[1,48] Although treatment of ES, including chemotherapy and surgery and/or radiation, has evolved over the past few decades leading to improved survival for a subset of patients, progress has halted for others. Controversies remain in the management of high-risk ES and other SRC sarcomas, in part driven by an incomplete understanding of their high-risk biological features and their relatively lower incidence, which have limited the feasibility of rigorous clinical trials for the smaller high-risk ES populations and rarer SRC sarcoma subtypes. Principles surrounding several such controversies are presented here, providing a foundation of both evidence and remaining questions for future studies in the endeavor to improve outcomes in these high-risk sarcomas.

Frontline chemotherapy for Ewing sarcoma. Building on a series of trials over the previous few decades, the landmark randomized phase III studies AEWS0031 and EURO EWING 2012 (EE2012) established the use of vincristine, doxorubicin, and cyclophosphamide (VDC) alternating with ifosfamide and etoposide (IE) in a biweekly interval compressed dosing schedule as standard-of-care frontline

TABLE 2. Overview of Relevant Completed and Ongoing Clinical Trials in CS

Trial	Trial Phase	Intervention	Drug Class	Type of Tumor	Status + Efficacy
Schwartz et al[36]	II	Cixutumumab + temsirolimus	IGF-1R antibody and mTOR inhibitor	STS Bone sarcoma CS (n = 38)	Completed mPFS: 5.2 months mOS: 13.6 months
Tawbi et al[33]	II	Pembrolizumab	PD-1 inhibitor	STS Bone sarcoma CS (n = 5)	Completed mPFS: 8 months mOS: 12 months
Chow et al[20]	II	Pazopanib	MTKI	CS (n = 47)	Completed mPFS: 7.9 months mOS: 17.6 months
Tap et al[28]	I	Ivosidenib	IDH1 inhibitor	CS (n = 21)	Completed mPFS: 5.6 months mOS: NA
Pollack et al[34]	I/II	Pembrolizumab + doxorubicin	PD-1 inhibitor	Advanced anthracycline-naïve sarcoma; CS (n = 4)	Completed mPFS: not reported mOS: not reported
Duffaud et al[21] REGOBONE	II	Regorafenib	MTKI	CS (n = 46)	Completed mPFS: 5 months mOS: 11.7 months

Abbreviations: CDK4/6, cyclin-dependent kinase 4/6; CS, chondrosarcoma; HDAC, histone deacetylase; IDH, isocitrate dehydrogenase; IGF-1R, insulin-like growth factor 1 receptor; mOS, median overall survival; mPFS, median progression-free survival; MTKI, multityrosine kinase inhibitor; mTOR, mammalian target of rapamycin; NA, not available; OS, overall survival; STS, soft tissue sarcoma.

chemotherapy for patients with localized ES, with an associated 5-year event-free survival (EFS) of 73% for AEWS0031 and a 3-year EFS of 67% for EE2012.[49-52] Several retrospective studies have further demonstrated the feasibility of interval compressed VDC/IE in adults with localized ES, with an estimated median 5-year EFS of 79%

and toxicity similar to that observed in trials with primarily pediatric enrollment.[53,54]

Studies over the past several decades, however, have failed to identify novel frontline therapeutic combinations to improve outcomes in metastatic ES. Although early studies using a VDC backbone in metastatic ES observed a response rate of 73%, only 30% of patients remained disease-free after 3 years.[55] The addition of IE, the antiangiogenic combination of vinblastine and celecoxib, or the IGF-1R inhibitor, ganitumab, to a VDC backbone, intensification of chemotherapy dose or schedule, or use of high-dose chemotherapy (HDC) with autologous stem-cell transplant (SCT) have not demonstrated a convincing improvement in EFS beyond this unacceptably low benchmark.[49,56-62] As new therapeutic strategies are desperately needed in metastatic ES, controversies remain in the optimal management of these high-risk patients beyond the use of a VDC chemotherapy backbone.[183,184]

Second- and subsequent-line chemotherapy in Ewing sarcoma. Outcomes in recurrent ES are poor, with fewer than 20% of patients surviving beyond 5 years, and chemotherapy options remain limited in this setting. The rEECur trial, a multiarm, multistage, phase II/III randomized study, compared survival and toxicity of four chemotherapy regimens in recurrent ES. Using a probability-based Bayesian approach and multiple pairwise comparisons, gemcitabine and docetaxel (GD) and irinotecan and temozolomide (IT) arms were closed in first- and second-interim assessments, respectively, because of observed lower overall response (OR) and shorter EFS.[63,64] Topotecan and cyclophosphamide (TC) and high-dose ifosfamide (IFOS) were then compared in a phase III analysis, with findings demonstrating a survival benefit in favor of IFOS.[65] The results from pairwise comparisons (Table 3) confirmed that GD in recurrent ES was associated with the poorest outcomes. Other comparisons favored greater EFS and OS with the use of TC over IT and with IFOS over TC, but demonstrated more favorable OS with IT compared to IFOS. However, some pairwise comparisons included a small number of patients, which may limit interpretation of these findings.[66] This framework efficiently studied the activity of these four regimens in recurrent ES. As IFOS, TC, and IT are all active regimens, the choice of therapy for second-line or beyond in recurrent ES should include consideration of individual patient factors and goals of care. The use of carboplatin and etoposide is now being explored in an ongoing arm of the rEECur study, and a new arm evaluating the combination of IFOS and lenvatinib is soon to open.

MTKIs are another established therapy option in recurrent ES. With targets including VEGF (vascular endothelial growth factor), PDGF (platelet-derived growth factor), KIT and RET, treatment with regorafenib in this population was associated with the mPFS of 11.4-14.8 weeks and OS of 34.9-53 weeks in recent trials, REGOBONE and SARC024.[67,68] Use of cabozantinib, a MTKI with targets including MET and VEGF, was associated with PRs in 25.6% of patients and a best response of stable disease (SD) in an additional 48.7% of patients. mPFS and OS were 4.4 and 10.2 months, respectively, in the CABONE trial.[69]

Despite the value of data obtained on short-term outcomes from these select studies, acknowledgment of the low rates of long-term survival in recurrent ES is critical, and accordingly, clinicians should support clinical trial enrollment in this setting when feasible.

HDC and SCT in ES. The use of HDC, in combination with autologous SCT (auto-SCT), has been an active area of interest, investigation, and debate for several decades. Multiple retrospective and single-arm studies, despite differences in initial conditioning therapy, have shown promising outcomes in patients with high-risk and refractory ES.[70-79]

For primary metastatic disease, several studies have explored the use of multiagent induction chemotherapy, followed by local control and consolidation HDC/SCT. With this approach, the Italian and Scandinavian Sarcoma Groups (ISG/SSG) observed 5-year EFS and OS rates of 43% and 52%, respectively.[80] A similar study from the Société Française des Cancers de l'Enfant demonstrated a 5-year EFS of 37% and OS of 38%.[81] Further analysis revealed that patients with lung-only metastases had an encouraging EFS rate of 52%, whereas the presence of bone metastases, without bone marrow involvement, was associated with an EFS rate of 36%. Using this framework in patients with bone, bone marrow, or multifocal metastases, which included induction of vincristine, ifosfamide, doxorubicin, and etoposide (VIDE)/vincristine, dactinomycin, and ifosfamide (VAI) and HDC with busulfan/melphalan before auto-SCT, the Euro-EWING R3 99 trial observed a 3-year EFS of 27% and OS of 34%.[62] However, none of those trials were randomized. Other studies exploring HDC and auto-SCT for patients with newly diagnosed metastatic disease revealed less encouraging results.[82] Among these, the randomized controlled R2Pulm trial studied the use of HDC/SCT in patients with lung-only metastatic disease but showed no benefit for the strategy over standard chemotherapy in combination with whole-lung irradiation, and toxicity, not surprisingly, was greater for those who received HDC/SCT.[83] The EuroEwing2008 also failed to demonstrate a benefit for the addition of treosulfan/melphalan in patients with very high-risk ES.[58]

Use of HDC/SCT has also been evaluated in patients with localized ES and poor response to induction therapy. The ISG/SSG group III protocol observed a 5-year EFS rate of 72% in poor responders who received intensified treatment with HDC/SCT, which compared favorably to those with a

TABLE 3. Available Data From rEECur Study

Chemotherapy Regimen	First Interim Analysis (18)	Second Interim Analysis (19)	Phase III Assessment[a] (third interim analysis) (20)
Gemcitabine/docetaxel (n = 72) (*v* regimens A, B, C)	ORR: 11.5% mPFS: 3 months (95% CI, 1.6 to 8.0) mOS: 13.7 months (95% CI, 10.1 to 23.9) Pairwise comparisons favored other arms for ORR and PFS		
Irinotecan/temozolomide (n = 127) (*v* regimens A, B)		ORR: 20% mPFS: 4.7 months (95% CI, 3.4 to 5.7) mOS: 13.9 months (95% CI, 10.6 to 18.1) Pairwise comparisons favored other arms for ORR, PFS, and OS	
Topotecan/cyclophosphamide (n = 162)			ORR: not reported mEFS: 3.5 months (95% CI, 2.1 to 5.1) mOS: 10.5 months (95% CI, 7.2 to 15.0)
High-dose ifosfamide (n = 78)			ORR: not reported mEFS: 5.7 months (95% CI, 3.8 to 6.9) mOS: 16.8 months (95% CI, 11.3 to 20.9)

NOTE. Regimens A, B, and C included irinotecan/temozolomide, cyclophosphamide/topotecan, and high-dose ifosfamide. Regimens A and B included cyclophosphamide/topotecan and high-dose ifosfamide.

Abbreviations: mEFS, median event-free survival; mOS, median overall survival; mPFS, median progression-free survival; ORR, overall response rate.

[a]Data are presented for third interim analysis on the basis of data presented at the ASCO 2022 Plenary Session.

poor response who received only standard therapy (33%), although again patients were not randomly assigned.[84] The R2Loc trial, a randomized study of HDC (busulfan/melphalan) and auto-SCT versus standard seven cycles of VAI for high-risk patients (with localized disease and a poor response to induction therapy), resulted in significant improvements in rates of 3-year (69% *v* 56.7%) and 8-year (60.7% *v* 47.1%) EFS and 3-year (78% *v* 72.2%) and 8-year (64.5% *v* 55.6%) OS.[85] More severe acute toxicities were seen in the HDC groups. The impact of HDC in patients receiving interval compressed VDC/IE is currently unknown, and its use, particularly in the United States, remains limited.

Although no randomized trials have explored the use of HDC in recurrent ES, several retrospective studies have, including one of 196 patients with relapsed or refractory ES, that reported superior post-relapse survival and mOS in patients who received HDC (67.9% at 2 years and 76 months, respectively) in comparison with those who received non-HDC chemotherapy (20.5% at 2 years and 10.5 months).[86] Other retrospective studies have reported similar outcomes among patients with relapsed ES treated with HDC and auto-SCT.[87] Until prospective randomized studies can help answer the question of benefit from HDC and auto-SCT in recurrent ES, Windsor et al[86] proposed a prognostic scoring system that, with validation, may help guide clinical decision making in this population.

Finally, there has been some interest in exploring allogeneic transplantation in patients with ES. However, data supporting its use remain limited and, in at least one study, did not appear to improve outcomes over auto-SCT.[88]

Management of other SRC sarcomas. Non-ES SRC sarcomas, including *EWSR1*–non-*ETS* fusion, *CIC*-rearranged, *BCOR*-rearranged, and unclassified round cell sarcomas, share a degree of morphologic or clinical similarity to ES but are now recognized as unique molecularly defined sarcoma subtypes (Table 1).[1,48,89] As such, the question arises of whether treatment of these other SRC sarcomas should mirror that of ES or whether tailored approaches are needed.

Most common of these, *CIC*-rearranged sarcomas often present as a deep soft-tissue tumor in the extremity and are associated with a more aggressive clinical course than ES, with an estimated 3-year OS rate of 56.5% and 20.4% in localized and advanced disease, respectively.[89-91] The optimal approach to chemotherapy in *CIC*-rearranged sarcomas is yet to be defined as most reports in the literature are based on retrospective cohorts or case series, but there is recognition that these tumors are minimally responsive to chemotherapy. Both the GRACefUl collaboration and a

retrospective French study explored chemotherapy response rates across *CIC*-rearranged sarcomas, reporting similar OR in patients whether treated with an ES-based therapy (VDC/IE or VIDE; 46%-57.9%) or a soft-tissue sarcoma–based regimen (doxorubicin, ifosfamide, mesna; 30%-56%). However, a long-term survival plateau was observed in patients with metastatic *CIC*-rearranged sarcoma treated with ES-based therapy, with three patients surviving for up to 48 months.[91] Smith et al[93] and Connolly et al[94] additionally reported on a small number of cases of metastatic *CIC*-rearranged sarcomas with prolonged survival after treatment with ES-based chemotherapy. Patients with recurrent *CIC*-rearranged sarcomas have limited therapeutic options, with clinical benefit (SD + PR) from several sarcoma-based therapies observed in only 8 of 37 patients studied in the GRACefUI collaboration, although PRs were reported in two patients using gemcitabine-based chemotherapy in the aforementioned French study.[91,92]

BCOR-rearranged sarcomas are the second most common SRC sarcoma, with a tendency to arise from long and flat bones in the majority of cases and a strong male predilection (Table 1).[1,48] These are genomically distinct from ES but display patterns of chemosensitivity and outcomes similar to those of ES, and reports from several case series support the use of ES-based chemotherapy in *BCOR*-rearranged sarcoma.[95-97] In the GRACefUI cohort, the rate of OR in localized *BCOR-CCNB3*–rearranged sarcoma treated with an ES-based regimen was 70%, although there were no responses observed in the two patients with metastatic disease after ES-based therapy. Three-year OS was 92.2% in patients with *BCOR-CCNB3* rearrangements.[90]

Emerging Strategies in Osteosarcoma and ES

Osteosarcoma and ES have effective initial therapies that often lead to symptom reduction and necrosis of primary tumor. In combination with local control, these therapies have demonstrated substantial improvements in survival when compared with local control measures alone in patients with localized disease.[98,99] Because of the rapid natural history of resected-only osteosarcoma, usually with development of numerous pulmonary metastases in under 6 months, we can conclude that chemotherapy is able to eliminate subclinical osteosarcoma cells outside the surgical field in about half of patients.[100-104] As detailed above, EFS in patients with localized ES has also markedly improved with chemotherapy.[105] However, there has been little change in the agents used and outcomes for patients with metastatic bone sarcoma and for patients with recurrent disease. A series of phase II studies of single-agent cytotoxic chemotherapy have been conducted and lack sufficient efficacy to further evaluate. These negative studies have served as the null hypothesis for current phase II studies in measurable disease.[106,107] Similarly, historical relapse rates for lung-only metastatic disease serve as the null hypothesis for adjuvant osteosarcoma trials.[107] The rEECur trial detailed above adds important data to our understanding of combination therapy in relapsed ES.

Why have recent attempts to improve survival through the addition of active cytotoxic or novel agents to frontline therapy in high-risk populations failed?[59,108-113] At present, we identify agent activity only through responses or delayed EFS, metrics for a dominant cancer cell population without focusing on agents with the potential to eliminate the residual population persisting during temporary complete responses. Increasingly, there are insights into these populations, and a translational path for agents that can affect the small populations resistant to VDC/IE or MAP (methotrexate, doxorubicin and cisplatin) chemotherapy is needed.[114-118,183,184]

ES. ES, defined here as including the characteristic *FET-ETS* translocations, has a clear target: the novel fusion oncoprotein. Although the normal functions of the fusion proteins are in mRNA stabilization (*FLI1*) and DNA binding (*EWSR*), the fusion globally changes transcription. When combined with a limited set of second hits, such as aneuploidy of particular arms or loss of function of *TP53* or *STAG2*, ES occurs.[119-126] Thus, targeting this central driver is rational, although challenging, as the fusion couples an intrinsically disordered protein to a transcription factor.[127] Trabectedin, mithramycin, TK216, and LSD1 inhibitors can affect *EWSR-FLI1* epigenetic reprogramming.[127-133] Table 4 compiles selected trials with a focus on ES or osteosarcoma. RNA interference, protein degraders, and immunotherapy directed to the novel epitope are also potential strategies to target the oncoprotein.

RNA transcription, processing, and translation involve CDK9, CDK12, and CDK13, among many other proteins. This class has shown preclinical promise both alone and in combinations with oncoprotein or growth factor targeting with trials underway.[134-136] The similarly named but differently functioning cell cycle proteins CDK4 and CDK6 have also been identified in several screens as potential targets unrelated to the fusion oncoprotein. CDK4 and CDK6 inhibitor trials are ongoing, many in combination with relapsed ES chemotherapy regimens.[137,138]

ES is more sensitive to DNA-damaging agents, with poly (ADP-ribose) polymerase (PARP) inhibition being seen as a possible therapeutic strategy. However, single-agent trials did not demonstrate efficacy, and incorporation of combination therapies to maximize DNA damage is associated with dose-limiting toxicity.[139-143] Further insights may provide a pathway for this initially very encouraging preclinical signal of activity.[144-147] ATR (Ataxia-Telangiectasia mutated and Rad3-related kinase) inhibitors and other agents that target DNA damage remain potential strategies.

As mentioned above, MTKIs have a clinical signal of activity in recurrent ES.[68,69] Along with oral administration and a manageable side effect profile, MTKIs are an appealing

TABLE 4. Selected Ongoing Trials Investigating Novel Targets in Ewing Sarcoma and Osteosarcoma

Pathway/Target/Agent	Trial (NCT No.)
Ewing sarcoma	
Fusion oncoprotein Trabectedin	NCT04067115: SARC037: A Phase I/II Study to Evaluate the Safety of Trabectedin in Combination With Irinotecan in Ewing Sarcoma Patients
LSD1 inhibition	NCT03600649: Clinical Trial of SP-2577 (Seclidemstat) in Patients With Relapsed or Refractory Ewing or Ewing-related Sarcomas
TK216	NCT02657005: TK216 in Patients With Relapsed or Refractory Ewing Sarcoma
CDK9	NCT03604783: First-in-Human Study of Oral TP-1287 in Patients with Advanced Solid Tumors
CDK4/6	NCT03709680: Study of Palbociclib Combined With Chemotherapy in Pediatric Patients With Recurrent/Refractory Solid Tumors
PARP	NCT04901702: Study of Onivyde With Talazoparib or Temozolomide in Children With Recurrent Solid Tumors and Ewing Sarcoma
PARP	NCT02813135: European Proof-of-Concept Therapeutic Stratification Trial of Molecular Anomalies in Relapsed or Refractory Tumors (ESMART): Arm D: Olaparib + irinotecan, Arm H: Olaparib and ATR inhibitor
MTKI	NCT05093322: A Study of Surufatinib in Combination With Gemcitabine in Pediatric, Adolescent, and Young Adult Patients With Recurrent or Refractory Solid Tumors
Osteosarcoma	
MTKI	NCT05691478: A Study to Test the Addition of the Drug Cabozantinib to Chemotherapy in Patients With Newly Diagnosed Osteosarcoma
Surfaceome—HER2	NCT04616560: Trastuzumab Deruxtecan for the Treatment of HER2+ Newly Diagnosed or Recurrent Osteosarcoma
Surfaceome—GD2	NCT02502786: A Phase II Study of Humanized Monoclonal Antibody 3F8 (Hu3F8) With Granulocyte-Macrophage Colony Stimulating Factor (GM-CSF) in the Treatment of Recurrent Osteosarcoma
Immunostimulatory	NCT04974008: Osteosarcoma Maintenance Therapy With OST31-164 (OST-164-01)
Cell cycle	NCT04833582: A Study of ZN-c3 in Combination With Gemcitabine in Subjects With Osteosarcoma NCT04040205: Abemaciclib for Bone and Soft Tissue Sarcoma With Cyclin-Dependent Kinase (CDK) Pathway Alteration NCT03242382: Trial of Palbociclib in Second Line of Advanced Sarcomas With CDK4 Overexpression (PalboSarc)
DNA damage	NCT04417062: Phase II Trial of Olaparib in Combination With Ceralasertib in Patients With Recurrent Osteosarcoma
PD-1 + PARP	NCT04544995: Dose Escalation and Cohort Expansion Study of Niraparib and Dostarlimab in Pediatric Participants with Solid Tumors
PD-1 + TKI	NCT04803877: SARC038: Phase 2 Study of Regorafenib and Nivolumab in Osteosarcoma NCT05019703: Atezolizumab and Cabozantinib for the Treatment of Adolescents and Young Adults With Recurrent or Metastatic Osteosarcoma, TACOS Study NCT05182164: Combination of Pembrolizumab and Cabozantinib in Patients With Advanced Sarcomas (PEMBROCABOSARC)
PD-1 + epigenetic	NCT03628209: Nivolumab or Nivolumab and Azacitidine in Patients With Recurrent, Resectable Osteosarcoma

Abbreviations: ATR, Ataxia-Telangiectasia mutated and Rad3-related kinase; HER2, human epidermal growth factor receptor 2; MTKI, multitargeted tyrosine kinase inhibitor; PARP, poly (ADP-ribose) polymerase; TKI, tyrosine kinase inhibitor.

choice for further investigation in clinical trials either as single-agent maintenance or in combination with chemotherapy. The surfaceome proteins expressed uniquely on ES cells, and thus good immunotherapy targets, remain an interesting strategy as well.[148]

Promising agents for ES were recently reviewed, and a framework was proposed to improve translation into clinical benefit.[149] We are increasingly appreciating the heterogeneity and dynamism of solid tumors through analyses of resistant populations and peripheral blood biomarkers, such as ctDNA.[116,117,150-152] Strategies that anticipate the minor resistant clones are needed to change PRs and delayed progression to durable remissions.

Osteosarcoma. Unlike ES, the targets for osteosarcoma are less clear, and next-generation sequencing has not clarified a therapeutic strategy. Fundamentally, osteosarcoma has

recurrent tumor suppressor loss with nearly all cases having loss of *TP53* activity that is currently not amenable to pharmacologic intervention.[153,154] Finding actionable targets has been difficult because of the complexity of the genome, tumor cell heterogeneity, and the variation in osteosarcoma tumor microenvironments. Explorations into targets on both the cell surface and the kinome, evaluating the altered cell cycle that is present in nearly all osteosarcoma, investigating DNA damage responses with the rearranged genome, and surveying the immune landscape are current strategies in osteosarcoma therapy.[153,155-159]

MTKIs show potential for the treatment of osteosarcoma. Although these agents inhibit several pathways concurrently, inhibition of angiogenesis by hindering VEGF receptor seems to be a shared mechanism. Several clinical trials exploring a MTKI as a single agent have demonstrated activity in excess of the PFS duration specified as having activity when compared with historical relapsed trials.[21,69,107,160,161] Further trials with a MTKI in combination with chemotherapy and as maintenance therapy are underway and planned.

Agents targeting surface proteins in osteosarcoma, such as B7H3 GD2, EGFR, and human epidermal growth factor receptor 2 (HER2), either as antibody-drug conjugates or using chimeric antigen receptor (CAR) T cells is another approach being explored, and considerations for the target, linker, and chemotherapy payload should be considered when evaluating the efficacy data.[156,162-170]

Both *RB1* loss and CDK4 amplification have been observed in osteosarcoma cell lines, patient-derived xenograph models, and patient samples.[158,171,172] Preclinical trials have shown inhibition of osteosarcoma cell lines and efficacy in patient-derived xenograph models with a CDK4 inhibitor supporting trials that include osteosarcoma.[171,173] WEE1 inhibitors have a track record of preclinical activity and are being combined with second-line chemotherapy.[175] Inhibiting DNA damage repair mechanisms may reduce chemoresistance and is being evaluated in a study combining PARP and ATR inhibitors.[175,176]

To our knowledge, to date, the role for immunotherapy remains undefined in osteosarcoma. Unfortunately, there is not a signal of activity with single-agent immune checkpoint inhibitors; several combination studies with MTKIs will provide efficacy data for this combination.[33] Innovative studies attempting to stimulate tumor-associated macrophages, collecting tumor-infiltrating lymphocytes from a patient's tumor and then reinfusing them back into the patient, the use of CAR T cells, and natural killer cell therapies are all being explored.[177-182]

In summary, the optimal therapy of metastatic and recurrent ES and osteosarcoma remains elusive. Ongoing preclinical and clinical research may identify agents with activity against these bone sarcomas. Heterogeneity and a focus on agents with activity in the selected resistant clones after primary therapy must be addressed to improve outcomes for these patients.

CONCLUSION

Over the past several decades, preclinical and translational research has positively transformed our understanding of tumor biology and therapeutic vulnerabilities of sarcomas. However, many questions and controversies remain in the optimal management of patients with these aggressive bone sarcomas, and clinical translation of novel targets into patient benefit has been challenging.

This argues for novel approaches to clinical trial design, the importance of correlative biomarker analysis, and greater international collaboration across scientific and pediatric and adult oncology communities in the mission to improve outcomes for these patients.

Current Therapeutic Targets in Cancer Cachexia: A Pathophysiologic Approach

Kunal C. Kadakia, MD[1,2]; Jill M. Hamilton-Reeves, PhD, RD, CSO[3,4]; and Vickie E. Baracos, PhD[5]

overview

Significant progress in our understanding of cancer cachexia has occurred in recent years. Despite these advances, no pharmacologic agent has achieved US Food and Drug Administration approval for this common and highly morbid syndrome. Fortunately, improved understanding of the molecular basis of cancer cachexia has led to novel targeted approaches that are in varying stages of drug development. This article reviews two major thematic areas that are driving these pharmacologic strategies, including those targeting signal mediators at the level of the CNS and skeletal muscle. Additionally, pharmacologic strategies are being tested in combination with targeted nutrients, nutrition therapy, and exercise to treat cancer cachexia. To this end, we highlight recently published and ongoing trials evaluating cancer cachexia therapies in these specific areas.

INTRODUCTION

Cancer cachexia remains a prevalent complication in the late stages of most cancers and can develop early in the course of others (eg, pancreatic, gastroesophageal, lung).[1] Cachexia is a hypercatabolic state characterized by anorexia and progressive wasting of adipose and skeletal muscle tissue. These complications cause reductions in physical functioning, health-related quality of life, poor tolerance to anticancer therapies, and decreased survival. Despite some randomized trials, no pharmacologic agent has yet achieved US Food and Drug Administration (FDA) approval, highlighting the urgent need for effective therapies.[2]

The incidence of cancer cachexia varies significantly by cancer site and stage.[3] Patients with upper GI and thoracic cancers often present with features of cachexia at diagnosis whereas other common malignancies such as breast and prostate typically develop cachexia during advanced stages of the disease. Notably, there can be significant interpatient variation independent of cancer site and stage, and new diagnostic tools continue to be explored to enhance early identification and understanding of individual cachexia susceptibility.[4,5]

Although diagnostic criteria continue to be updated and revised, they are based on the presence and extent of weight loss in clinical practice.[2,6,7] Cachexia is often overlooked and underestimated.[8] Certain elements of cachexia are amenable to clinical management, including control of pain and symptoms such as nausea, which severely impair dietary intake. Nutritional deficits may be substantial, and while cachexia is not entirely reversible by diet alone, nutrition therapy can be partially effective. Unfortunately, cachexia often progresses unabated, culminating in a state of extreme depletion, at which late point interventions cannot reverse the wasting process. As such, accurately identifying cachexia early has significant therapeutic implications. Cancer imaging can be exploited to detect muscle depletion; however, there are currently no laboratory tests with established clinical utility that confirms the diagnosis of cachexia although progress related to potential biomarkers continues.[9-11]

It is now clear that there is significant tumor-organ and interorgan crosstalk involved with the development and progression of cancer cachexia (Fig 1); this is a roadmap for understanding the therapeutic strategies in current clinical trials (Table 1).

In this study, we provide a concise review of the major thematic areas driving current cachexia treatment strategies. These include pharmacologic agents targeting signal mediators within CNS controls of appetite/satiety as well as drugs designed to interrupt catabolic signaling in skeletal muscle. Drugs may be delivered alone or in combination with exercise and nutrition therapy to restore anabolic growth factor–signaling, nutrient-signaling, and contractile-signaling pathways in muscle.

Currently, investigational new therapies for cachexia are focused on the regulation of appetite/satiety and on the regulation of skeletal muscle mass (Table 1). Regulatory authorities in the United States, Europe, and other countries do not have an international standard for approval of the current generation of cachexia therapies. Regulators require that the agent reverse or slow cachexia, as demonstrated by blunting of weight loss and/or of radiologically define skeletal muscle and fat mass. Regulators additionally require a

PRACTICAL APPLICATIONS

- Cancer cachexia is a highly morbid condition that negatively affects quality of life, reduces tolerance to anticancer therapy, and confers poor survival. Despite this, there is no current US Food and Drug Administration–approved pharmacological agent for cachexia.
- Improved understanding of the complex interactions among tumor byproducts and their effect on multiple organs provide rationale for targeted therapeutic strategies currently in development.
- The CNS is integral in the pathogenesis of cancer cachexia through varied mechanisms including hypothalamic and neuroendocrine alterations that promote and accelerate anorexia and peripheral tissue catabolism.
- Skeletal muscle wasting, a hallmark of cachexia, involves dysregulation at the level of the skeletal muscle cell induced by specific tumor-derived and inflammation-derived factors, anticancer therapies, and deficits of nutrients and contractile activity.
- The complex pathophysiology of cachexia indicates that a multifaceted approach involving reversal of anorexia, inhibition of catabolic changes, as well as nutrition and rehabilitation will be vital for effective therapies.

demonstrable clinical benefit (coprimary end point), and it is this category of end points that have engendered the most debate. This accounts for the fact that cachexia trials in phase I/II typically have multiple secondary outcomes to better define the potential clinical benefit(s).

THE CNS AND CANCER CACHEXIA

The neurobiology of cancer is an area of investigation that explores the bidirectional nature of cancer on the nervous system which receives and paradoxically amplifies the effect of cytokines via multiple aberrant pathways.[12] Increasing evidence highlights the role of the CNS in the pathophysiology of cancer cachexia including hypothalamic inflammation, neuroendocrine perturbations, and increased sympathetic nervous system tone, all of which are potential and ongoing targets for drug development (Fig 2).[13,14]

Therapeutic Target: Anorexia, Satiety, and Hypothalamic Inflammation

The hypothalamus is a critical brain structure responsible for maintaining homeostasis and regulates food intake and systemic energy balance via inputs from a broad variety of stimuli. In cancer, hypothalamic neurons contribute to peripheral wasting by two major mechanisms. First, tumor-derived inflammatory cytokines (eg, interleukin-6 [IL-6]) influence specific endocrine hormones (eg, leptin and ghrelin) which alter food intake by downregulation of orexigenic/prophagic and upregulation of anorexigenic responses.[13] Second, the hypothalamus aberrantly responds to peripheral inflammation by central production of other proinflammatory mediators (eg, interleukin-1 beta [IL-1β] and leukemia inhibitory factor [LIF]) which activates the hypothalamic-pituitary-adrenal axis (HPA) and contributes directly to loss of muscle and adipose tissue.[14] This combination of reduced appetite along with stimulation of tissue catabolism represents the pathologic result of hypothalamic inflammation.

Melanocortin Type 4 Receptor Antagonists

The melanocortin-4 receptor (MC4R) is a G-protein coupled receptor that is regulated by endogenous MC4R agonists in response to the nutritional/energy state. When activated, pro-opiomelanocortin neurons release the endogenous MC4R agonist, α-melanocyte–stimulating hormone (α-MSH), which binds to MC4R and activates signaling to reduce appetite and food intake.[15] The agouti-related peptide is a competitive antagonist of α-MSH produced in the hypothalamus during an energy deficit, leading to increased appetite via suppression of MC4R signaling. As such, inhibitors of MC4R signaling (ie, melanocortin antagonists) are putative mechanisms to reduce anorexia. Early clinical studies of melanocortin antagonists in animals showed anticachexia properties relatively consistent but were limited by their requirement for intracerebroventricular administration to achieve efficacy.[16,17]

TCMCB07. A novel MC4R antagonist, TCMCB07 is a synthetic peptide that has blood-brain barrier transport properties. An initial study involving rat cachexia models confirmed that peripheral routes of administration stimulated food intake, reduced weight loss, and preserved fat and lean mass.[18] These data have led to an ongoing phase I study of TCMCB07 given as a subcutaneous injection in healthy volunteers to assess the safety, tolerability, and pharmacokinetics.

PF-07258669. An orally bioavailable small-molecule MC4R antagonist, PF-07258669, has been evaluated in animal models and increased food consumption and weight gain.[19] Two phase I studies in healthy volunteers have been conducted with this agent. The initial study of 29 patients completed accrual in 2021, and the results are yet to be published.

Therapeutic Target: Neuroendocrine Changes and Cachexia

Central endocrine organ regulation is largely mediated by the HPA and hypothalamic-pituitary-gonadal axes (Fig 2). Cachexia-inducing factors such as tumor-derived cytokines (eg, tumor necrosis factor-α [TNF-α] and IL-6) as well as centrally produced proinflammatory mediators (eg, IL-1β) activate both pathways. Stimulation of the HPA axis leads to excessive production of cortisol which increases peripheral skeletal

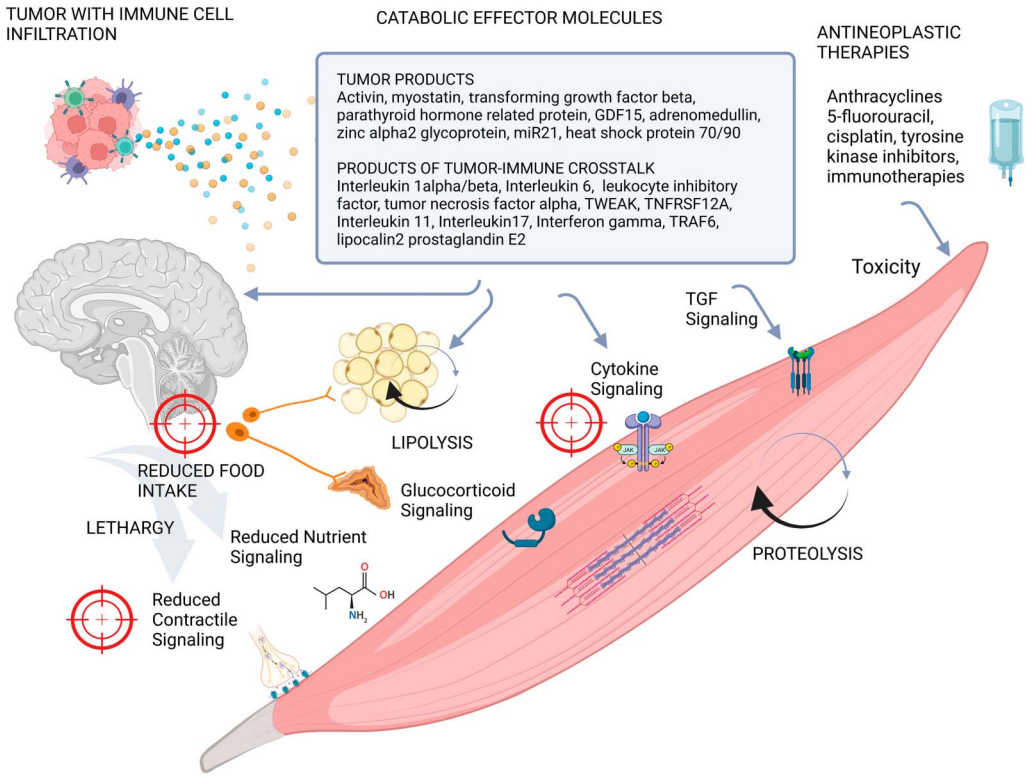

FIG 1. Interorgan relationships in cancer cachexia: Where do the therapeutic targets reside? Cachexia is initiated by a complex mixture of tumor-derived catabolic factors and proinflammatory molecules generated through tumor crosstalk with associated stromal cells and the immune system. Some of these factors act directly on muscles and adipose tissues to elicit excess catabolism (eg, lipolysis inducers adrenomedullin, zinc α2 glycoprotein). Skeletal muscle catabolism is induced by proinflammatory cytokines, eicosanoids, and transforming growth factor-β (TGFβ) family effectors (eg, activin A, myostatin). Alteration of CNS functions further induces catabolism. Altered CNS outputs are neural (eg, activation of sympathetic output to adipocytes) and neuroendocrine (activation of adrenal with increased catabolic glucocorticoid signaling to muscle). Behavioral changes associated with malignant disease include reduced food intake and lethargy, reducing anabolic growth factor, nutrient, and contractile activity signaling. Systemic therapy–associated wasting is a powerful impetus to the overall loss of skeletal muscle, via specific toxic actions at the cellular level. GDF15, growth differentiation factor 15; miR, microRNA; TNF, tumor necrosis factor; TNFRSF12A, TNF receptor superfamily member 12A; TRAF6, TNF receptor–associated factor 6; TWEAK, TNF-related weak inducer of apoptosis.

muscle wasting via complex changes in the regulation of genes involved with muscle catabolism (eg, *Foxo1*, *Slc39a14*, *Cebpd*) as well as inactivation of key regulators of muscle anabolism, such as the mammalian target of rapamycin (mTOR).[20,21] Important central mediators involved with failure of food intake are putative therapeutic targets, including growth differentiation factor 15 (GDF15) and ghrelin receptor agonists.

GDF15 Antibodies

The cytokine, GDF15, directly contributes to anorexia by binding to glial cell-derived neurotrophic factor family receptor α-like (GFRAL) within the feeding center of the brainstem.[22,23] The mechanisms by which the GDF15-GFRAL axis contributes to cachexia includes an anorexia-mediating effect suggested by the presence of GFRAL receptors in the vomiting center of the brain (area postrema) leading to nausea as well as the direct influence of GDF15 on peripheral fat metabolism via autonomic outflow to the liver.[24,25] GDF15 is higher in patients with evidence of cachexia than noncachectic patients, and platinum therapies further increase the expression of GDF15.[26-28] Recombinant GDF15 reduces food intake and promotes weight loss via anorexia and promotion of lipolysis; subsequent blockade of GFRAL signaling reverses these changes.[28,29] As such, inhibition of the GDF15-GFRAL axis is an area of active investigation.

PF-06946860. This anti-GDF15 humanized monoclonal antibody binds to GDF15, inhibiting its interaction with the GFRAL receptor. Subcutaneous administration at varying doses in healthy participants observed no serious treatment-emergent adverse effects although the results have not been formally published. A phase IB 12-week study of PF-06946860 in patients with non–small-cell lung cancer

TABLE 1. Targeted Therapeutic Trials in Cancer Cachexia

Therapeutic Target Area and Mechanism of Action	Compound/Route of Administration	Phase and Design	N	Population	Primary/Secondary Outcomes[a]	Study Start and Completion Dates[b]	Results	Clinical Trial No.
CNS—appetite/satiety/hypothalamic inflammation								
Melanocortin type 4 receptor antagonists	TCMCB07, SQ	I, randomized, double-blind, placebo-controlled	97	US, healthy volunteers	Safety/pharmacokinetics	July 12, 2022-January 2023	Recruiting	NCT05529849
Melanocortin type 4 receptor antagonists	PF-07258669, oral	I, randomized, double-blind, placebo-controlled	29	US, healthy volunteers	Safety/pharmacokinetics	March 16, 2021-August 25, 2021	Completed and results awaited	NCT04628793
Anti-GDF15	Ponsegromab (PF-06946860), SQ	II, randomized, double-blind, placebo-controlled	168	US, advanced cancers (NSCLC, pancreatic, CRC) with elevated GDF15 levels	Change in body weight/physical activity	November 21, 2022-May 15, 2025	Recruiting	NCT05546476
Anti-GDF15	Ponsegromab (PF-06946860), SQ	I, randomized, double-blind, placebo-controlled	63	US, healthy volunteers	Safety/pharmacokinetics	July 30, 2018-September 18, 2019	Completed and results awaited	NCT03599063
Anti-GDF15	Ponsegromab (PF-06946860), SQ	Pilot, randomized, double-blind, placebo-controlled	18	US and Canada, advanced cancers (NSCLC, pancreatic, CRC, prostate, breast, or ovarian)	Change in Cancer-Related Cachexia Symptom Assessment-Appetite score/fatigue and safety	May 11, 2021-August 9, 2022	Completed and results awaited	NCT04803305
Anti-GDF15	Ponsegromab (PF-06946860), SQ	IB, nonrandomized	11	US, advanced cancers (NSCLC, pancreatic, CRC)	Safety/pharmacokinetics	November 17, 2020-March 30, 2022	Completed and results awaited	NCT04299048
Anti-GDF15	Ponsegromab (PF-06946860), SQ	I, randomized, double-blind, placebo-controlled	8	Japanese, healthy volunteers	Safety/pharmacokinetics	July 8, 2019-January 10, 2020	Completed and results awaited	NCT03974776
Anti-GDF15	NGM120, SQ	I, randomized, double-blind, placebo-controlled	92	Australia, healthy volunteers	Safety	January 29, 2018-March 11, 2019	Completed and results awaited	NCT03392116
Anti-GDF15	NGM120, SQ	I/II, randomized, double-blind, placebo-controlled	75	US, advanced solid cancers	Safety/Bodyweight and Skeletal muscle index change	October 16, 2019-January 2025	Recruiting	NCT04068896
Anti-GDF15	AV380, IV and SQ	I, randomized, double-blind, placebo-controlled	56	US, healthy volunteers	Safety/pharmacokinetics and GDF15 levels by dose and serum level of AV380	February 22, 2021-January 2022	Active, not recruiting	NCT04815551
Anti-GDF15	CTL002, IV	I/II, nonrandomized	155	Europe, advanced cancers after progression on one previous anti-PD-1/PD-L1 treatment	Safety/change in appetite via questionnaire, BMI, and skeletal muscle index	December 9, 2020-May 31, 2025	Recruiting	NCT04725474
Ghrelin receptor agonist	Anamorelin, oral	III, randomized, double-blind, placebo-controlled	318	US and international, unresectable stage III or stage IV NSCLC	Weight change and 5-item Anorexia Symptom Subscale	December 18, 2018-Janaury 31, 2023	Active, not recruiting	NCT03743064
Ghrelin receptor agonist	Anamorelin, oral	III, randomized, double-blind, placebo-controlled	316	US and international, unresectable stage III or stage IV NSCLC	Weight change and 5-item Anorexia Symptom Subscale	December 18, 2018-February 2023	Active, not recruiting	NCT03743051

(Continued on following page)

TABLE 1. Targeted Therapeutic Trials in Cancer Cachexia (Continued)

Therapeutic Target Area and Mechanism of Action	Compound/Route of Administration	Phase and Design	N	Population	Primary/Secondary Outcomes[a]	Study Start and Completion Dates[b]	Results	Clinical Trial No.
Ghrelin receptor agonist	Anamorelin, oral	II, randomized, double-blind, placebo-controlled	100	US, locally advanced or metastatic pancreatic cancer	Weight change/5-item Anorexia Symptom Subscale, survival, and Fatigue Subscale	September 30, 2022-December 31, 2023	Recruiting	NCT04844970
Dopamine and serotonin receptor antagonist	Olanzapine, oral	III, randomized, open-label *v* megestrol	360	US, advanced solid or hematologic cancers	Change in appetite	October 15, 2021-December 2024	Recruiting	NCT04939090
Skeletal muscle								
JAK2/STAT inhibitor	Ruloxitinib, oral	Pilot, nonrandomized	20	US, stage IV NSCLC	Safety/change in QOL and anorexia via questionnaire	February 23, 2022-February 2024	Recruiting	NCT04906746
Multimodality approach								
MENAC: anti-inflammatory, nutrient signaling, contractile work	Ibuprofen + ONS with EPA + nutritional counseling + exercise prescription	III, randomized, open-label *v* standard palliative care	240	US and international, advanced NSCLC or pancreas	Weight change	April 2015-September 2022	Active, not recruiting	NCT02330926
Nutrient signaling, anti-inflammatory	Arginine + omega-3 fatty acids	III, randomized, double-blind, placebo-controlled	200	US, bladder cancer	Postoperative complications/changes in body composition	February 21, 2019-May 1, 2026	Recruiting	NCT03757949
MIRACLE: anti-inflammatory, nutrient signaling, contractile work	Ibuprofen + omega-3 fatty acids + ONS + Bojungikki-tang + nutritional counseling + exercise prescription	II, randomized, open-label *v* standard palliative care	112	Korea, advanced NSCLC or GI cancers	Weight change and handgrip strength	January 31, 2020-June 30, 2022	Recruiting	NCT04907864
NEXTAC-III: ghrelin receptor agonist, nutrient signaling, contractile work	Anamorelin + nutritional counseling + home-based resistance training	II, randomized, open-label *v* SOC	90	Japan, advanced NSCLC or pancreas	Change in 6-minute walking distance	September 01, 2021-NP	Recruiting	jRCTs041210053

Abbreviations: BMI, body mass index; CRC, colorectal cancer; EPA, eicosapentaenoic acid; GDF, growth differentiation factor; IV, intravenous; JAK/STAT, Janus kinase-signal transducer and activator of transcription pathway; NP, not provided; NSCLC, non–small-cell lung cancer; ONS, oral nutritional supplement; QOL, quality of life; SOC, standard of care; SQ, subcutaneous.

[a]For phase I and II trials, select secondary outcomes focused on cachexia-related end points provided as available.

[b]For trials not completed, estimated study completion dates per ClinicalTrials.gov provided.

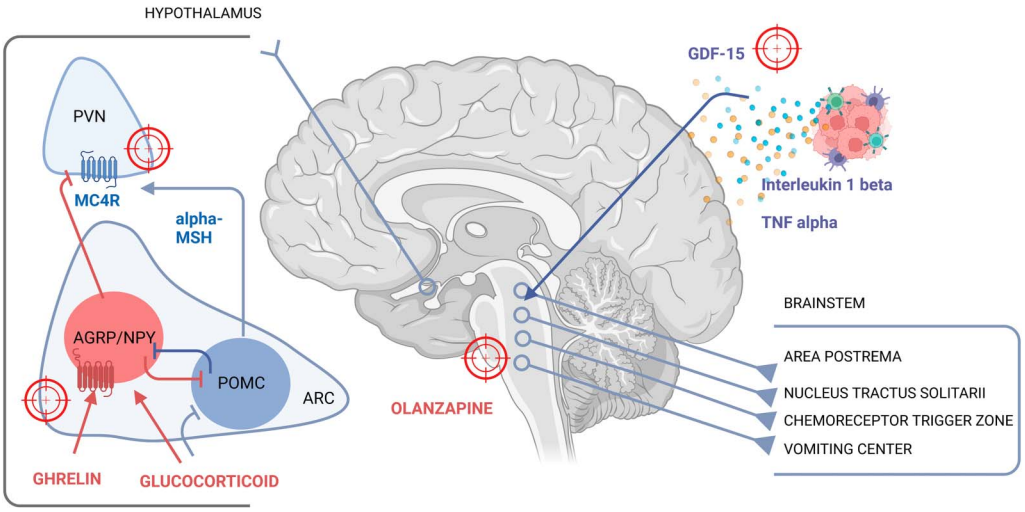

FIG 2. CNS-mediated mechanisms of cancer cachexia. Anorexia and excessive peripheral catabolism originate in part by tumor-induced and inflammatory changes in specific regions of the hypothalamus and brainstem. Cytokines (eg, IL1, TNFα) exert a profound inflammatory effect on the hypothalamus resulting in activation of anorexigenic neurons (ie, POMC) and inhibition of orexigenic neurons (ie, NPY). NPY neurons stimulate food intake in response to a variety of mediators including ghrelin. Ghrelin is a multifaceted gut hormone which activates the growth hormone secretagogue receptor (GHS-R). Ghrelin's hallmark functions are its stimulatory effects on food intake, fat deposition, and growth hormone release. POMC neurons inhibit food intake by the production of α-MSH, a neuropeptide of the melanocortin family, which acts via type 4 melanocortin receptors (MC4R) in the paraventricular nucleus (PVN). Small molecular weight, orally active agonists of GHS-R, and antagonists of MC4R have been developed for the indication of anorexia/cancer cachexia. Growth differentiation factor (GDF15) is overexpressed by some cancers and inhibits food intake by activating the GFRAL-RET signaling pathway in the brainstem area postrema and nucleus tractus solitarii. Advanced stage cancers may be associated with persistent non–chemotherapy-related nausea, and clinical management of these symptoms with antiemetic regimens is recommended to enable food intake. High-dose corticosteroids activate NPY neurons and inhibit POMC neurons; however, this is limited as a therapeutic approach because of secondary toxicity including muscle atrophy, poor glycemic control, and thrombosis. AGRP, agouti-related peptide; GDF15, growth differentiation factor 15; IL1, interleukin-1; NPY, neuropeptide Y; POMC, pro-opiomelanocortin; TNFα, tumor necrosis factor-α; α-MSH, α-melanocyte–stimulating hormone.

(NSCLC), pancreatic, and colorectal cancer and a 6-week, randomized, double-blind study of 18 patients with advanced cancer, anorexia, and elevated circulating GDF15 levels have completed accrual, and results are awaited.

Three other anti-GDF15 agents are under investigation in phase I trials (*NGM120, AV380, CTL-002*) and include cachexia-related end points (Table 1).

Ghrelin Receptor Agonists

Ghrelin, produced primarily in the stomach, is a peptide hormone and an endogenous ligand for the growth hormone secretagogue receptor (GHS-R) in the hypothalamus.[30] Ghrelin activates NPY neurons (ie, orexigenic action) and promotes GI motility. It has pleiotropic effects on bodyweight and fat mass as well as food intake. GHS-R activity increases growth hormone secretion from the pituitary which stimulates insulin-like grow factor from the liver contributing to muscle mass anabolism and stimulation of lipogenic pathways.[31] The overall effect is stimulation of energy intake and inhibition of expenditure. As such, ghrelin receptor agonists continue to be studied to reduce the burden of cancer cachexia.

Anamorelin. Anamorelin hydrochloride is a selective ghrelin receptor agonist. ROMANA 1 and ROMANA 2 were randomized, double-blind, placebo-controlled phase 3 trials in patients with advanced NSCLC that evaluated anamorelin at 100 mg daily and observed benefit (Table 2). Both studies detected statistically significant and clinically modest increases in lean body mass (as measured by dual-energy x-ray absorptiometry [DXA]). In addition, statistically significant improvements in bodyweight and patient-reported anorexia-cachexia were found as measured by the Functional Assessment of Cancer Therapy anorexia-cachexia scale over a 12-week period. However, both studies failed to meet the coprimary end point of improved handgrip strength.[32] ROMANA 3, an extension of these studies, included 513 patients with preserved functional status after completing 12 weeks of therapy and found that anamorelin continued to be well tolerated with improvements in bodyweight and

maintenance of anorexia-cachexia scores through 24 weeks although no difference in handgrip strength was observed.[33]

In December 2020, anamorelin (ONO-7643) was approved in Japan for cancer cachexia, specifically in NSCLC, gastric cancer, pancreatic cancer, and colorectal cancer on the basis of the results from two Japanese prospective studies. The largest was a randomized, double-blind, placebo-controlled trial of 174 patients with stage III/IV NSCLC and showed improvement in the primary end point of lean body mass over a 12-week period but no difference in handgrip strength or 6-minute walk test.[34] The other study was a nonrandomized study involving 50 patients with advanced stage GI cancers and showed similar improvement in lean body mass assessed by DXA.[35] Multiple other studies evaluating anamorelin are ongoing (Table 1).

Macimorelin. A phase II randomized study of oral macimorelin, a ghrelin receptor agonist, in advanced cancers was closed early because of poor accrual and study relocation. The investigators observed a modest numerical difference in bodyweight and quality of life with macimorelin (n = 15) compared with placebo (n = 10) over a 1-week period.[36]

SKELETAL MUSCLE AND CANCER CACHEXIA

Tumor and Cancer Therapy Act to Cause Muscle Wasting

Disease-related and treatment-related factors seem to simultaneously drive catabolism in muscle (Fig 1).

This is in part mediated by the CNS, via suppression of dietary intake and HPA activation. Tumor and inflammation-derived products also have panoply of direct, receptor-mediated effects on muscle. On top of the tumor effects, systemic therapy–associated skeletal muscle wasting is emerging as a powerful impetus to the overall loss of skeletal muscle experienced by patients with cancer. Clinical findings are based on precise, specific measures of muscle loss over the duration of chemotherapy, targeted therapy, and immunotherapy. Nearly all therapeutic classes of anticancer agents induce quantitatively important muscle loss, independent of tumor response. Parallel experimental studies provide understanding of the specific molecular basis of wasting, which can include inhibition of protein synthesis, proliferation and differentiation, and activation of inflammation, reactive oxygen species, autophagy, mitophagy, apoptosis, necroptosis, protein catabolism, fibrosis, and steatosis in muscle.

Anabolic-Catabolic Regulation in Muscle

Mechanisms underlying skeletal muscle growth, maintenance, and atrophy are well-characterized. A network of signaling pathways coordinates muscle protein balance (Fig 3). This network includes an anabolic arm, reliant on growth factors, contractile activity and nutrient signaling via a pathway involving phosphatidylinositol-3 kinase (PI3K), serine/threonine protein kinase (Akt), and the mTOR, which leads to muscle protein synthesis. The catabolic arm is characterized by multiple signaling cascades, connected ultimately to transcriptional control of genes involved in autophagy and to ubiquitin-mediated proteasomal degradation of myofibrils.

Cytokine mediators of muscle wasting include IL-6, which is a key regulator of skeletal muscle, IL-1, TNF, IFNγ, LIF, and TNF-related weak inducer of apoptosis (TWEAK; Fig 3). These factors signal through their respective cell surface receptors and activate selective transcription factors, which in turn promote the transcription of ubiquitin-proteasome and autophagy components (Fig 3). In addition to inflammatory cytokines, the TGF-β family ligands myostatin, GDF11, and activins are negative regulators of skeletal muscle mass, which primarily signal via type 2 activin receptors (ACV2R) to induce muscle wasting. Activin-A is produced by both tumor and immune cells. In models of cancer cachexia, inhibiting ACV2R reverse muscle wasting and prolongs survival, even with continued tumor growth.[37]

Endemic Muscle Loss During Systemic Cancer Therapy

With the advent of diagnostic imaging-based methods, it has become possible to precisely characterize muscle loss during treatment. The precision of these measures of tissue change over time is excellent when performed by trained experts, with precision values in the range of approximately 1.3 cm^2 for a determination of muscle cross-sectional area and a least significant change value of approximately 2.9 cm^2 (ie, the smallest change detectable above measurement error).[38]

Two meta-analyses describe muscle loss during cancer treatment.[39,40] Wang et al[39] reviewed 25 studies (N = 2,706 participants) of neoadjuvant chemoradiotherapy for gastroesophageal cancers, finding a pooled loss of skeletal muscle index (SMI, cm^2/m^2) of –2.47 cm^2/m^2 (ie, losses of approximately 10%). Jang et al[40] reviewed 15 studies (N = 2,662 participants) with diverse cancers (lung, GI, head and neck, gynecological) and treatment regimens. The mean difference in SMI was –2.72 cm^2/m^2. The highest mean losses were up to 11% over the treatment plan (approximately 3 months), seen among patients with pancreatic cancers on leucovorin, fluorouracil, irinotecan, and oxaliplatin and in patients receiving neoadjuvant chemoradiation for head and neck or esophageal cancers. Rinninella et al[43] reviewed 11 studies of muscle loss during tyrosine kinase inhibitor (TKI) therapy but did not conduct a meta-analysis owing to a lack of consistency in the measures of muscle loss. Studies to date include muscle changes during treatment with sorafenib, regorafenib, sunitinib, lenvatinib, pazopanib, axitinib, and vandetanib. These investigations were generally consistent in finding loss of skeletal muscle, although the authors speculated that effect sizes might vary according to differences in the specificities of TKI for different tyrosine kinases in the growth factor receptor signaling pathways.

TABLE 2. Results From Phase III Randomized Trials of Anamorelin

Trial Name	Phase and Design	Population	Primary Outcomes	Primary Results (95% CI) or (SE)	Key Secondary Outcomes	Secondary Results (95% CI) or (SE)	Study Start and Completion Dates	Clinical Trial No.
ROMANA 1 (N = 484)	III, randomized, double-blind, placebo-controlled	US and international, unresectable stage III or stage IV NSCLC	Coprimary end point: change in LBM (kg) and HGS (kg)	LBM: anamorelin 0.99 (0.61 to 1.36) *v* placebo –0.47 (–1.00 to 0.21), $P < .0001$; HGS: –1.10 (–1.69 to –0.40) *v* –1.58 (–2.99 to –1.14), $P = .15$	Change in bodyweight (kg), symptoms of anorexia-cachexia and fatigue[a], and overall survival[b]	Mean bodyweight: anamorelin 2.2 (0.33) *v* placebo 0.14 (0.36), $P < .0001$; anorexia: 4.12 (0.75) *v* 1.92 (0.81), $P = .0004$; fatigue: 0.26 (0.89) *v* -1.91 (0.93), $P = .054$; survival: 8.9 (8.3 to 9.8) *v* 9.17 months (7.9 to 11.0), $P = .47$	July 8, 2011-January 28, 2014	NCT01387269
ROMANA 2 (N = 495)	III, randomized, double-blind, placebo-controlled	US and international, unresectable stage III or stage IV NSCLC	Coprimary end point: change in LBM (kg) and HGS (kg)	LBM: anamorelin 0.65 (0.38 to 0.91) *v* placebo –0.98 (–1.49 to –0.41), $P < .0001$; HGS: -1.49 (–2.06 to –0.58) *v* –0.95 (–1.56 to 0.04), $P = .65$	Change in bodyweight (kg), symptoms of anorexia-cachexia and fatigue[a], and overall survival	Mean bodyweight: anamorelin 0.95 (0.39) *v* placebo –0.57 (0.44), $P < .0001$; anorexia: 3.48 (0.94) *v* 1.34 (1.03), $P = .0016$; fatigue: 1.37 (1.17) *v* 1.23 (1.29), $P = .86$; survival: 8.9 (8.3-9.8) *v* 9.17 months (7.9-11.0), $P = .47$	July 14, 2011-October 31, 2013	NCT01387282
Katakami et al (N = 174)	III, randomized, double-blind, placebo-controlled	Japan, unresectable stage III or stage IV NSCLC	Change in LBM (kg)	LBM: anamorelin 1.38 (0.18) *v* placebo –0.17 (0.17), $P < .0001$	Change in bodyweight (kg), symptoms of appetite[c] and fatigue[d], 6MWT (meters)	Mean bodyweight: anamorelin 1.06 (0.2) *v* placebo –0.5 (0.19), $P < .0001$; appetite: 0.7 (0.1) *v* 0.3 (0.1), $P = .005$; fatigue: 1.7 (0.7) *v* 1.4 (0.7), $P = .717$; 6MWT: 11.7 (7.8) *v* 11.7 (7.2), $P = .998$	May 2014-January 2015	JapicCTI-142451

Abbreviations: 6MWT, 6-minute walk test; HGS, handgrip strength; IV, intravenous; LBM, lean body mass; NSCLC, non–small-cell lung cancer.

[a]12-item anorexia-cachexia scale of the Functional Assessment of Anorexia/Cachexia Therapy has scores ranging from 0 to 48, and higher scores suggest lower levels of anorexia-cachexia.

[b]3-item fatigue scale of the Functional Assessment of Chronic Illness Therapy-Fatigue has scores ranging from 0 to 52, and higher scores suggest less fatigue.

[c]Appetite was a self-rated single item on a 1-5 scale, with a lower score indicating worse appetite.

[d]Cancer Fatigue Scale is a self-rated fatigue scale and has 15 items scored on a 1-5 scale for a maximum score of 60, with higher scores indicating more severe fatigue.

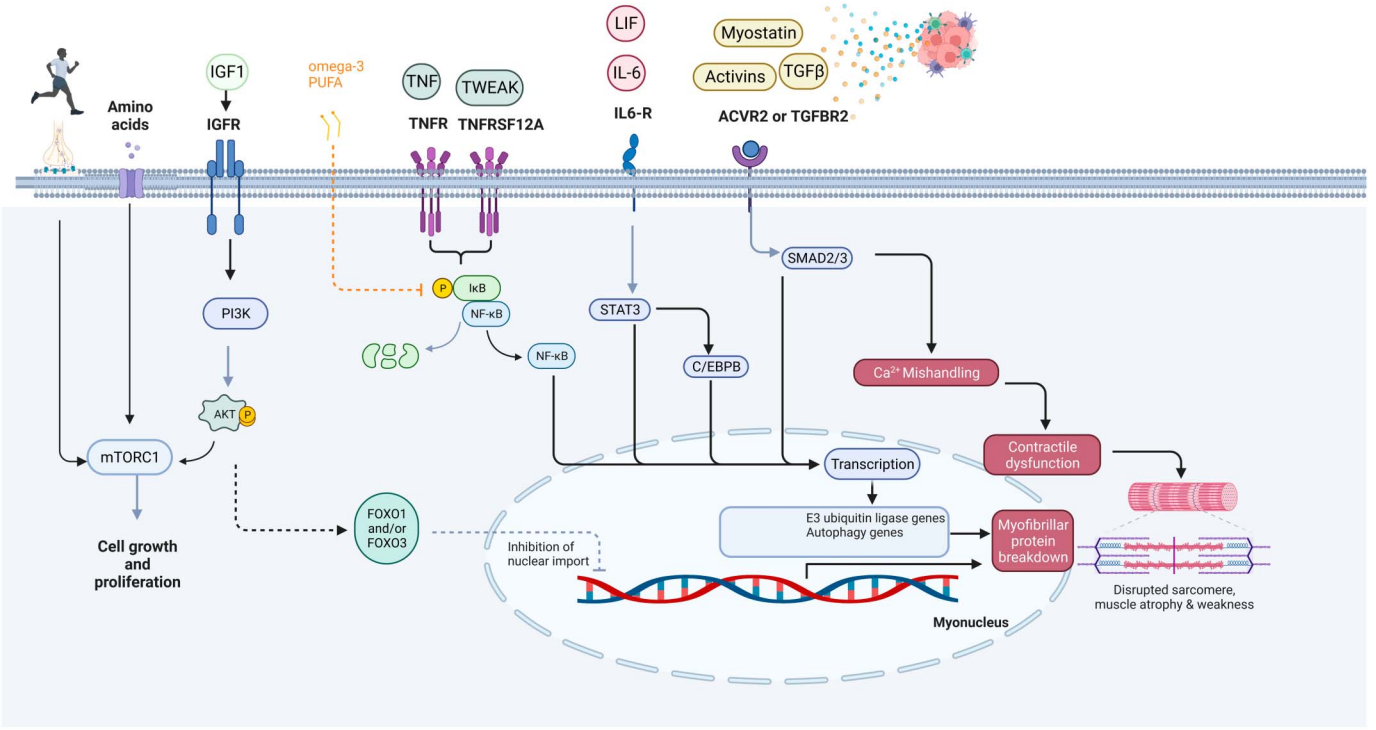

FIG 3. Signaling pathways involved in tumor-induced skeletal muscle atrophy. Signaling pathways involved in the control of muscle anabolism and catabolism. Protein synthesis, cell growth, and proliferation are normally maintained by growth factors, nutrients, and contractile activity. Anabolism is activated by downstream pathways that converge at the mTOR complex 1, a multicomplex protein able to activate transcription of hypertrophy genes. Phosphorylated AKT also blunts catabolic signaling via inhibition of *FoxO* and its downstream signaling to transcription of atrophy genes. Omega-3 PUFA suppress the dissociation of NF-κB/IκB and decrease the translation of atrophy genes in the nucleus induced by NF-κB. Protein breakdown is regulated by transcriptional regulation of atrophy genes, mediated by NF-kB, *STAT3*, *C/EBPβ*, and SMAD2/3 transcription factors. Tumor products and products of activated host immune cells induce atrophy, TNF-α, and TWEAK acting via downstream signaling that induces a dissociation of NF-κB/IκB complex and NF-κB translocation to the nucleus. IL-6 and LIF induce STAT3 and C/EBPβ signaling pathways, and TGF-β superfamily members (eg, myostatin, activin-A) activate SMAD2/SMAD3. ACVR2, activin receptor type 2; AKT, serine/threonine protein kinase; C/EBPβ, CCAAT/enhancer-binding protein-β; FoxO, forkhead box protein O complex; IκB, inhibitory subunit of NF-κB; IGF1, insulin-like growth factor-1; IGFR, IGF receptor; IL-6, interleukin-6; IL-6R, IL-6 receptor; LIF, leukocyte inhibitory factor, mTOR, mammalian target of rapamycin; mTORC1, mammalian target of rapamycin complex 1; PI3K, phosphatidylinositol-3 kinase; PUFA, polyunsaturated fatty acid; STAT3, signal transducer and activator of transcription 3; TGFBR2, TGF-β receptor type 2; TNF, tumor necrosis factor; TNFR, TNF receptor; TNFRSF12A, TNF receptor superfamily member 12A; TWEAK, TNF-related weak inducer of apoptosis.

In Figure 4, we present a summary of recent reports on loss of skeletal muscle during cancer treatment. Most regimens associated with muscle loss (range, 0% to –13.7%/100 days), except for neoadjuvant chemotherapy for breast cancer (regimens including anthracycline, cyclophosphamide, and taxane) in three studies which were negative or showed a low rate of muscle loss.[41,44,45] This is perhaps expected since weight gain and not weight loss is common in breast cancer. By contrast, studies in advanced stage pancreatic cancer showed high intensity of loss –11.1% to –13.7%/100 days.[42,46]

A 10% muscle loss over approximately 100 days on a cancer therapy is a relatively intense rate of catabolism. By contrast, age-related muscle loss of 10% would be expected to take approximately 20 years in men and approximately 25 years in women.[56] Thus, muscle losses consequent to 100 days of cancer therapy are of similar magnitude to approximately 2 decades of age-related muscle depletion. Another point of reference is in critical care, where the mean overall rate of muscle loss of 1.75%/day (12%/week) was reported in a meta-analysis.[57]

Therapeutic Targets: Molecular Pathways of Treatment-Related Muscle Loss and JAK/STAT Inhibition

Off-target effects of systemic cancer therapies add to skeletal muscle loss experienced by patients with cancer, by a broad range of mechanisms related to their specific modes of action (Fig 5). Targeted therapies are a diverse class of inhibitors of intracellular signal transduction pathways involved in growth factor–mediated cell proliferation, such as PI3K, Akt, and mTOR. Members of the TKI class are

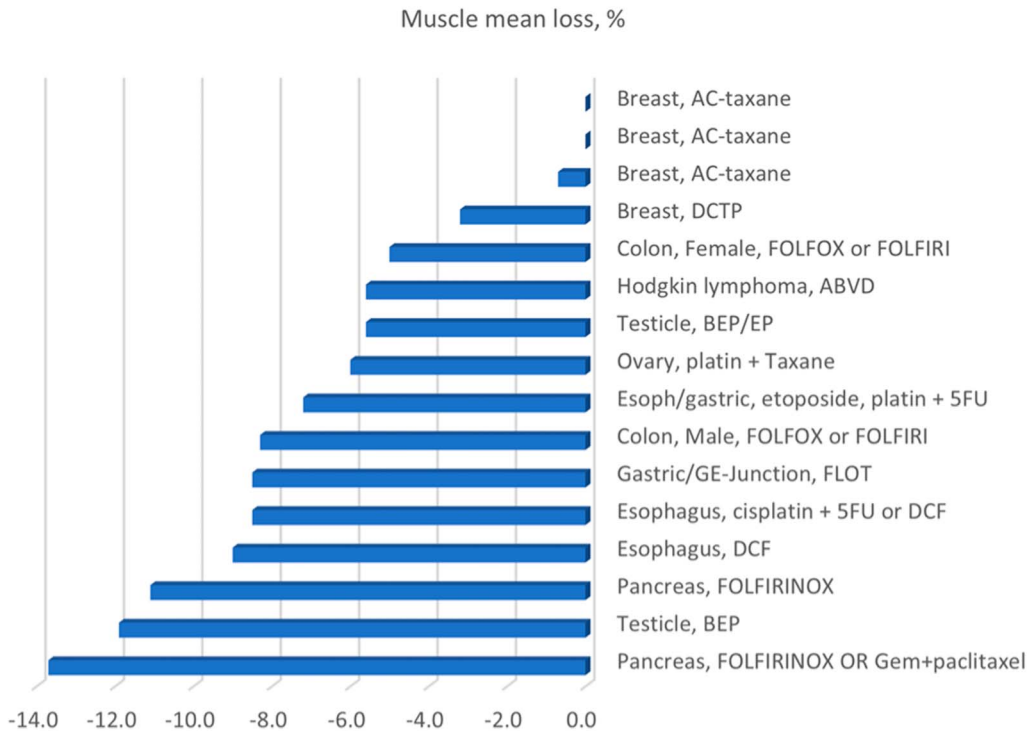

FIG 4. A summary of recent reports of muscle loss rates during systemic cancer therapies. Data are for muscle loss reported during standard regimens. Because of variations in scan interval, for purposes of comparison, author-reported mean muscle loss was converted to % lost per 100 days on treatment. Data are from existing studies.[41,42,44-55] ABVD, doxorubicin, bleomycin, vinblastine, and dacarbazine; AC, anthracycline and cyclophosphamide; BEP, bleomycin, etoposide, platinum; BEV, bevacizumab; DCF, docetaxel, cisplatin, fluorouracil; DCTP, docetaxel, carboplatin, trastuzumab, and pertuzumab; FLOT, fluorouracil, leucovorin, oxaliplatin, and docetaxel; FOLFIRINOX, leucovorin, fluorouracil, irinotecan, oxaliplatin; FOLFOX, leucovorin, fluorouracil, oxaliplatin; FU, fluorouracil; GE, gastroesophageal; Gem, gemcitabine.

predictably deleterious to muscle because the PI3K-Akt-mTOR pathway plays a key role in muscle protein synthesis. Cytotoxic antineoplastic agents induce a wide variety of cellular perturbations in protein turnover, proliferation, differentiation, and mitochondrial function. There is also evidence for fibrosis, loss of motor units, inflammatory cell infiltration, and fatty infiltration of muscle. Cisplatin remains the most intensively studied individual compound.[58,59] Cisplatin suppresses protein synthesis via an Akt protein kinase B (Akt)–dependent mechanism, which leads to p70S6k1 dephosphorylation. Cisplatin modifies mTORC1 and forkhead box O (FoxO)–dependent signaling cascades, enhances the transcription of atrophy genes, and synergistically activates the ubiquitin proteasome system and autophagy, resulting in myofibrillar degradation. Cisplatin also induces several changes contributing to atrophy and contractile dysfunction, H_2O_2 production, oxidative stress, increased/compromised Ca2+ dynamics, and desensitized excitability of action potentials, which seem likely to explain reduced force production and weakness.

Ruloxitinib. Among the pathways indicated in Figure 5, the JAK/STAT pathway, which is involved in signal transduction downstream of interleukin-6 and LIF, causes loss of muscle mass and function. There are a variety of FDA-approved inhibitors of JAK1/2 in trials related to myeloproliferative neoplasms as well as inflammatory diseases such as GVHD, rheumatoid arthritis, and critical illness myopathy.[60,61] Exercise, may in part, exert its anti-inflammatory action on muscle via the JAK-STAT pathway.[62] The JAK1/2 inhibitor ruxolitinib was created as an oral agent with the capacity to antagonize JAK/STAT signaling across cell types. In a phase I trial (Table 1), ruxolitinib will be evaluated in an open-label approach to antagonize JAK/STAT signaling as a means of curtailing cachexia progression in patients with stage IV NSCLC. This study will ensure an acceptable toxicity profile when ruxolitinib is used in patients with cancer cachexia. The use of ruxolitinib dose escalation in the study with frequent tissue and serum collections will permit us to better understand how important JAK/STAT signaling is to cancer cachexia.

NUTRIENT SIGNALING AND MULTIMODALITY APPROACHES FOR CANCER CACHEXIA

Reduction in food intake is strongly associated with weight loss, and this is not surprising given that total energy expenditure of patients with cancer is approximately 30 kcal/kg bodyweight/day with many patients showing moderately reduced and severely reduced food intake of the order of 22.2 ± 7.7 and 13.3 ± 7.7 kcal/kg/day, respectively. Attempts to correct anorexia and excess satiety in the CNS are underway (see Section, The CNS and Cancer Cachexia). However, the dietary intake of many patients with cancer has the potential to be optimized by engaging oncology-specific nutritionists and physical therapists who focus on raising intake of specific anabolic nutrients and timely clinical management of pain, and nutrition affect symptoms such as nausea and enable muscle anabolism through concurrent exercise.

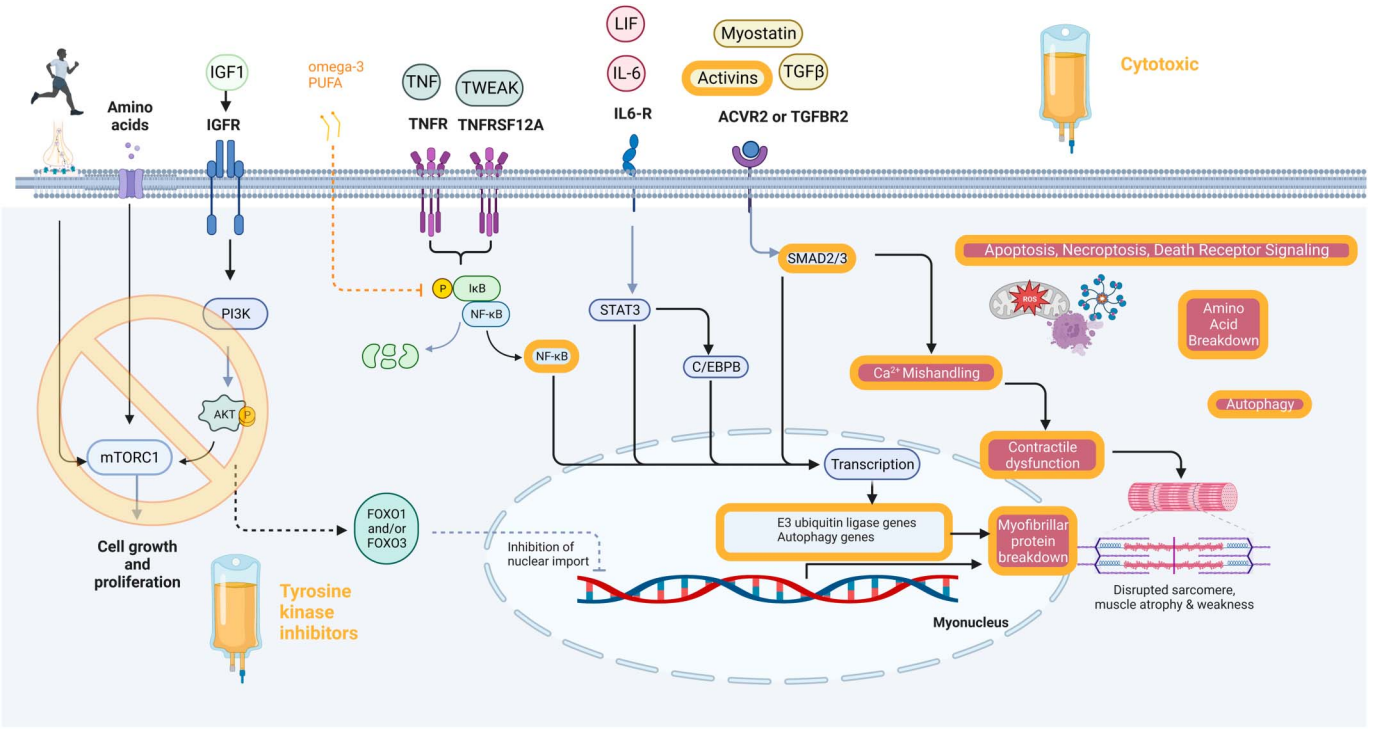

FIG 5. Signaling pathways involved in antineoplastic therapy–induced skeletal muscle atrophy. Cytotoxic cancer therapies induce transcriptional activation of pathways of myofibrillar destruction by the ubiquitin proteasome system, autophagy, and catabolism of amino acids. Apoptosis, necroptosis, and death receptor signaling are also activated, along with mitochondrial dysfunction and overproduction of reactive oxygen species. ACVR2, activin receptor type 2; AKT, serine/threonine protein kinase; C/EBPβ, CCAAT/enhancer-binding protein-β; FoxO, forkhead box protein O complex; IκB, inhibitory subunit of NF-κB; IGF1, insulin-like growth factor-1; IGFR, IGF receptor; IL-6, interleukin-6; IL-6R, IL-6 receptor; LIF, leukocyte inhibitory factor; mTORC1, mammalian target of rapamycin complex 1; PI3K, phosphatidylinositol-3 kinase; PUFA, polyunsaturated fatty acid; STAT3, signal transducer and activator of transcription 3; TGFBR2, TGF-β receptor type 2; TNF, tumor necrosis factor; TNFR, TNF receptor; TNFRSF12A, TNF receptor superfamily member 12A; TWEAK, TNF-related weak inducer of apoptosis.

Therapeutic Targets: Nutrient Signaling

For nutrients and their metabolites that are rate-limiting in key metabolic pathways, preventing any deficiencies may help preserve or restore metabolic homeostasis.

Omega-3 fatty acids. Omega-3 fatty acids, eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA), are naturally occurring in fish oil and are known to reduce inflammation. Several signaling pathways of omega-3 fatty acids action have been proposed as targeted nutrient signaling that could facilitate a mechanistic effect by elevating the resolution of inflammation while producing anti-inflammatory mediators, decreasing proinflammatory factors, reducing the activation of proteolytic pathways, and increasing appetite.[63]

The evidence for a therapeutic effect of supplementation with omega-3 fatty acids on cancer cachexia is inconclusive.[64] The effects of omega-3 fatty acids are likely dependent on timing, dose, and duration; therefore, meta-analyses cannot account for this variability across studies with the current evidence available. The timing of omega-3 fatty acids could be an important consideration with more recent studies showing potential benefits when the interventions are earlier in the progression of cancer cachexia or given before a catabolic trigger such as surgery.[65,66] Moreover, dose ranges vary greatly with an intake of >2 g/d (EPA + DHA) which is the amount needed to have an anti-inflammatory effect.[67] The most practical implications for dietary interventions in this population are to use strategies to increase adherence and to measure fatty acid biomarkers to account for variability expected in supplementation adherence. It is also noteworthy that many of the positive studies gave omega-3 fatty acids as part of an oral nutrition formulation, and 2020 ASCO Cancer Cachexia Guidelines suggest use of omega-3 fatty acids within foods as tolerated.[2]

Proteins/Amino Acids

Muscle depletion and catabolism are key physical features of cachexia. Tissue demands for amino acids become critical in times of stress, cancer, or traumatic injury (eg, surgery). Muscle protein is the main reservoir to replace blood amino acids when they are taken up by other tissues and will be catabolized to export amino acids to meet this need. Proteolysis in patients with cachexia can worsen with cancer

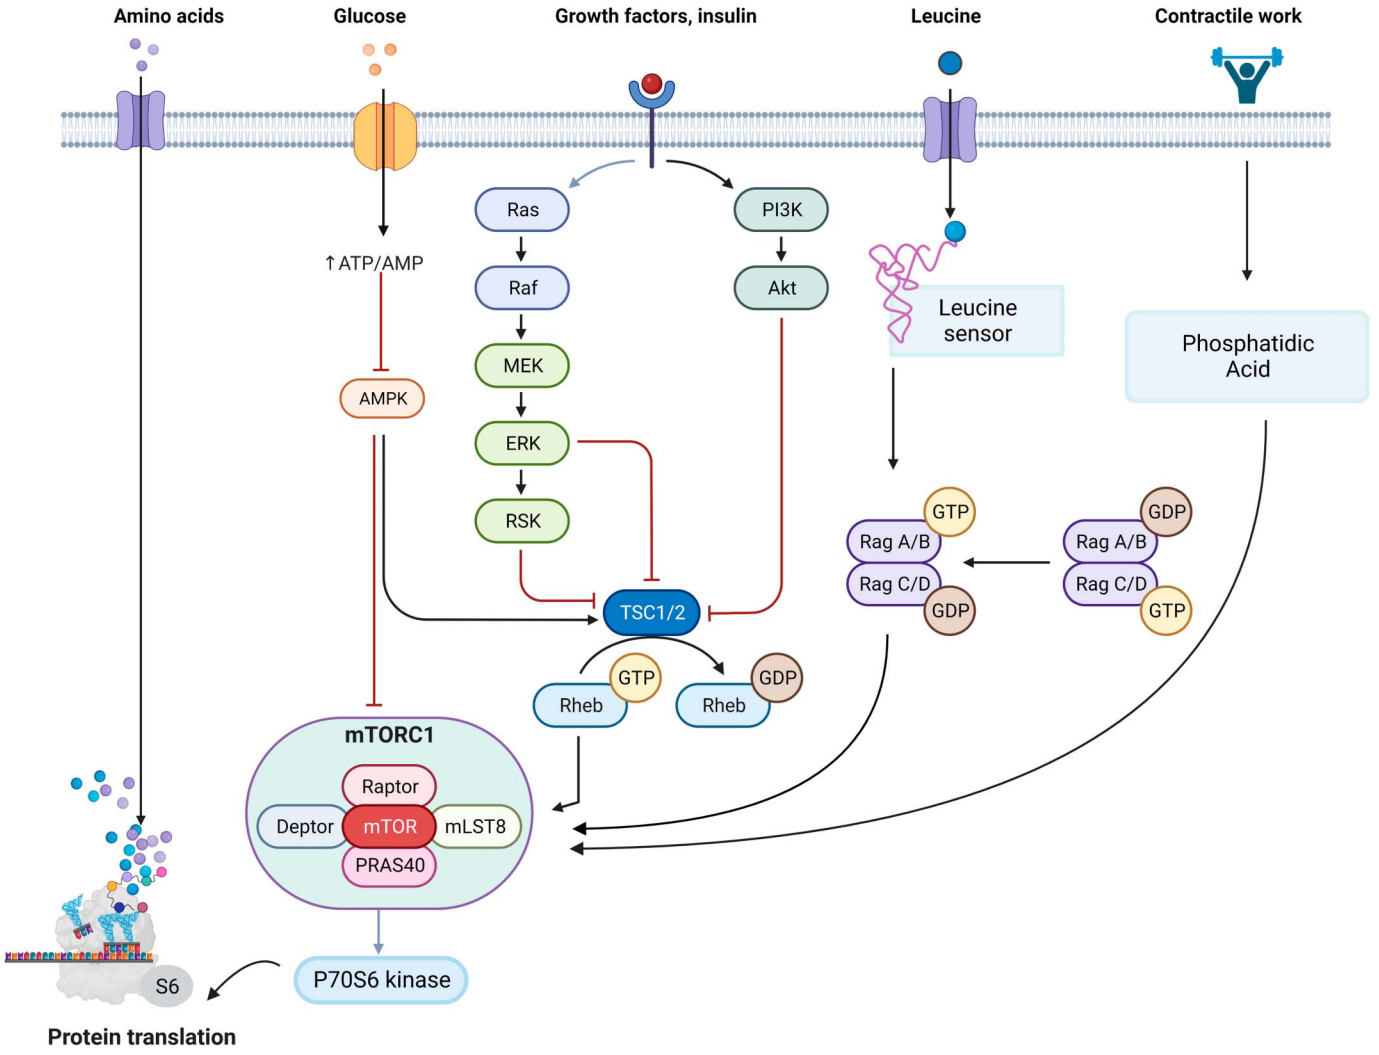

FIG 6. Pathways of nutrient-related, growth factor–related, and contraction-related signaling activate muscle protein synthesis. The growth factor–sensitive and nutrient-sensitive mammalian/mechanistic target of rapamycin complex 1 (mTORC1) is a master regulator anabolism in muscle cells. Signaling pathways activated by nutrients, growth factors, and contractile work are convergent to mTORC1, and activation of the complex requires both nutrients and growth factors to be present. Muscle protein biosynthesis requires availability of 20 amino acids, which are the substrate for the formation of protein. However, the branched chain amino acids, particularly leucine, also have a signaling action. Leucine sensing proteins, such as leucyl t-RNA synthetase, participate in the activation of mTORC1 via the activation of RagB/RagD. Contractile activity that is either high load (resistance training) or high torque (eccentric contraction) signals mTORC1 activation via formation of phosphatidic acid, the ζ isoform of diacylglycerol kinase is necessary for the mechanically induced increase in phosphatidic acid. On activation, mTORC1 will phosphorylate P70S6 kinase, which goes on to phosphorylate ribosomal protein S6 and initiate RNA translation. Akt, serine/threonine protein kinase; AMPK, AMP-dependent protein kinase; ATP/AMP, adenosine triphosphate/adenosine monophosphate; ERK, extracellular signal–regulated kinase; GDP, guanosine diphosphate; GTP, guanosine triphosphate; MEK, mitogen-activated protein kinase; mLST8, mammalian lethal with SEC13 protein 8; mTORC1, mammalian target of rapamycin complex 1; PI3K, phosphatidylinositol-3 kinase; PRAS40, proline-rich Akt substrate of 40 kDa; Raf, rapidly accelerated fibrosarcoma; Rag, recombination-activating genes; Ras, rat sarcoma; Rheb, RAS homolog enriched in brain; RSK, ribosomal S6 kinase; TSC1/2, tuberous sclerosis complex.

treatments depleting both essential and nonessential amino acids, which then become conditionally essential. Proteins are made from chains of essential and nonessential amino acids. When any single amino acid is deficient due to inadequate intake or a higher metabolic demand, then growth or nitrogen balance is compromised. Adequate supply of dietary protein is a prerequisite to maintain or gain skeletal muscle mass. Patients with cancer can have an anabolic response to eating protein. Higher dietary protein intake can increase protein synthesis by increasing systemic amino acid availability. Branched-chain amino acids (BCAA) are essential amino acids that are important for muscle, and arginine is an amino acid that becomes depleted in surgery (Fig 6).

BCAA/Leucine. Metabolic changes contributing to cancer cachexia are characterized by a net protein breakdown and an increased oxidation of BCAAs in the skeletal muscle to support gluconeogenesis and to supply amino acids for acute-phase protein synthesis in the liver.[68] A 2023 meta-analysis by Sideris et al[69] concluded that BCAA supplementation in patients with liver cancer during treatment led to higher albumin concentrations, but there were insufficient data to draw conclusions on improvement in lean mass. Leucine is more potent than isoleucine and valine in stimulating muscle protein synthesis, while it also decreases muscle protein degradation.[70]

Arginine. Arginine is a semiessential amino acid important for immune function. Normally, we obtain a small proportion of arginine from food and synthesize the remaining 70%-75% from citrulline or protein turnover. During cachexia or other catabolic and inflammatory conditions, arginine concentrations are depleted.[71] In patients with cancer, arginine supplementation demonstrated immunomodulating properties together with improvement in survival and malnutrition.[72] In a perioperative, randomized, controlled trial of patients with bladder cancer, 66% of patients had insufficient arginine before their radical cystectomy. Supplementing arginine in an oral nutritional supplement (ONS) product before and after this catabolic surgery prevented the arginine and ornithine depletion, in contrast to the control ONS group, and showed a trend toward preservation of muscle mass and led to favorable immunomodulation and lower postoperative infection rates.[66,73] A large retrospective study also reported lower postoperative infections with the same supplementation.[74] A phase III trial is currently underway to test the effects of this regimen which provides arginine and omega-3 fatty acids in an ONS versus a control ONS in a patient population at high risk for cachexia by evaluating 30-day postoperative complications, immune and nutrient biomarkers, and lean mass.

Physical activity. Exercise improves muscle mass and physical function in adults with cancer who are at risk of developing cachexia. The current evidence base is less clear for patients with cancer cachexia. A 2021 Cochrane review of four studies found no clear evidence that an exercise program alone or as a component of a multimodal intervention improved outcomes in patients with cancer cachexia.[75] By contrast, a 2022 review by Mavropalias et al[76] summarized the evidence from exercise training trials involving patients with cancer cachexia and noted several studies reporting improved outcomes of maintaining bodyweight and lean mass. Anabolic deficit may be partly addressed by maintaining physical activity. It is noteworthy that exercise improves the effectiveness of nutritional therapy and helps stimulate appetite in cachexia because of other advanced chronic illnesses such as chronic obstructive pulmonary disease. Acute exercise training affects molecular signaling pathways that support building muscle mass, and regular exercise training can lead to beneficial metabolic adaptations.[77] It is unlikely that physical activity without other supportive care can overcome cancer cachexia; however, data suggest that giving patients support to facilitate exercise training safely throughout the treatment spectrum is helpful.

Multimodality. Multimodal strategies, if pragmatic, are a logical approach to address the varied mechanisms driving cachexia. Nutrition and exercise training can help combat muscle loss if implemented earlier and might complement conventional care to help prevent cachexia. Evidence is not conclusive, and yet, it is clear that maintenance or building of muscle mass requires adequate energy, correction of nutrient deficiencies, and physical activity. A prehabilitation program using a multimodal approach that included exercise, nutrition counseling, and psychosocial support showed significant improvements in quality of life in a retrospective study.[78] A feasibility study with an exercise and nutrition intervention during first-line chemotherapy in patients with advanced pancreatic and lung cancer demonstrated safety and adherence.[79] These data have led to the phase II trial, called NEXTAC-III, currently in progress in Japan, which adds anamorelin to a multimodal strategy. Another multimodal phase II trial, called MIRACLE, is in progress in Korea using ibuprofen, omega-3 fatty acids, ONS, Bojungikki-tang (which mediates immune modulation), nutrition counseling, and an exercise intervention compared with conventional palliative care.[80] MENAC, a phase III multimodal trial, was conducted in Europe and the United States, and results are pending. In this trial, patients with lung or pancreatic cancers either received standard treatment for their cancer or standard treatment plus a home-based exercise regimen, ONS-containing EPA, and dietary guidance, along with daily ibuprofen. Accrual targets were met for this study in 2022, and results are expected in 2023. More well-designed multimodal trials focused on end points evaluating changes in body composition, nutrition and nutrient status, energy balance, and physical function are needed.[81]

CONCLUSION

The etiology of cachexia is multifactorial, with various procachectic abnormalities spanning the skeletal muscles, adipose tissues, immune, neural, endocrine, cardiac, respiratory, and GI systems. While much remains to be understood, investigational new therapies are directed at perturbations of appetite and satiety and at the relentless catabolism of skeletal muscle. Participation in clinical research of cachexia therapies will provide patients with access to the leading treatments currently in phase I, phase II, and phase III studies.

How to Make Evidence-Based Integrative Medicine a Part of Everyday Oncology Practice

Ting Bao, MD, MS[1]; Heather Greenlee, ND, PhD, MPH[2]; Ana Maria Lopez, MD, MPH[3]; Zachary O. Kadro, ND, MPH[2]; Gabriel Lopez, MD[4]; and Linda E. Carlson, PhD[5]

overview

Integrativety oncology (IO) is a "patient-centered, evidence-informed field of comprehensive cancer care that utilizes mind-body practices, natural products, and lifestyle modifications from different traditions alongside conventional cancer treatments." There is an urgent need to educate oncology health care providers on the fundamentals of evidence-based IO to meet the needs of people with cancer. In this chapter, we aim to provide oncology professionals with actionable guidance on the basis of the Society for Integrative Oncology (SIO)-American Society of Clinical Oncology (ASCO) guidelines on integrative medicine use during oncology visits to help alleviate symptoms and side effects in people with cancer during and after treatment.

Author affiliations and support information (if applicable) appear at the end of this article.

Accepted on April 4, 2023 and published at ascopubs.org on May 18, 2023: DOI https://doi.org/10.1200/EDBK_389830

INTRODUCTION

The term integrative oncology (IO) is defined by the Society for Integrative Oncology (SIO) as "a patient-centered, evidence-informed field of comprehensive cancer care that utilizes mind-body practices, natural products, and lifestyle modifications from different traditions alongside conventional cancer treatments."[1] Use of integrative therapies such as these by people with cancer has grown significantly over the past 50 years, from approximately 20% in the 1970s to the 80% range in 2017.[2] Concurrently, IO services at National Cancer Institute (NCI)-Designated Comprehensive Cancer Centers have increased from about 50% in 2009 to 80% in 2016.[3] This growth corresponds to a significant rise in integrative medicine research, expanding our understanding of the role of IO as part of evidence-informed, high-quality, personalized cancer care.

With high utilization of integrative therapies in populations with cancer, frequent requests from people with cancer, and the growing body of evidence for specific therapies, there is a need to enhance IO training opportunities for oncology professionals. Currently, oncology professionals are poorly equipped to guide people with cancer on evidence-based integrative medicine usage during and after anticancer treatments.[4] Moreover, the successful delivery of high-quality care will require providers to acknowledge the values and preferences of people with cancer to enable shared decision making. Thus, there is an urgent need to educate oncology health care providers on the fundamentals of evidence-based IO to meet the needs of people with cancer.

In this chapter, we aim to address this gap and provide oncology professionals with actionable guidance on the basis of the SIO-American Society of Clinical Oncology (ASCO) guidelines on integrative medicine use during oncology visits to help alleviate symptoms and side effects in people with cancer during and after treatment.

HOW TO INCORPORATE IO INTO PATIENT CARE

People with cancer and their families and/or caregivers may have questions about the role of IO approaches to support their cancer journey. Gaps in communication can occur when oncology providers do not ask their patients about integrative therapies and patients do not feel comfortable enough to initiate these kinds of conversations on their own.[5] Although clinicians may have experience with integrative approaches on the basis of their own health goals, it is important for oncology professionals to go beyond their personal experience in making recommendations for their patients. Knowledge regarding an evidence-informed framework can help oncology professionals guide people with cancer in making thoughtful decisions about integrative approaches. Such a framework ideally considers the aspects of safety and an understanding of the latest evidence and clinical practice guidelines.

People with cancer often struggle with multiple cancer- or treatment-related symptoms and side effects. People with cancer often turn first to their oncology health care team for guidance in managing these symptoms. They often prefer IO approaches because of their desire for nonpharmacologic and holistic health approaches which may align better with their personal health belief system.[6] More natural and holistic approaches are often perceived as less likely to cause harm or additional side effects. By discussing and recommending evidence-based integrative approaches as a first line of action

PRACTICAL APPLICATIONS

- This chapter provides oncology professionals with actionable guidance on the basis of the Society for Integrative Oncology (SIO)-American Society of Clinical Oncology (ASCO) guidelines on integrative medicine use during oncology visits to help alleviate symptoms and side effects in people with cancer during and after treatment.
- It provides guidance for oncology professions on structured approaches to advise and manage the safe and appropriate use of dietary supplements.
- It offers a summary of mind-body therapies to support people with cancer, which can be readily used in oncology practice.
- It offers a blueprint on how integrative oncology could become part of standard cancer care soon.

for addressing many symptoms, this approach meets the needs of people with cancer, gains their trust, and subsequently improves the quality of the professional relationship and the quality of life of people with cancer.

Questions about IO approaches may fall into any of the following categories: (1) managing symptoms, (2) supporting health and well-being, and (3) treating cancer. An awareness of these categories and the motivation of any given person seeking care can be helpful in guiding choices that support their interests. Effectively engaging people in discussions about their IO questions is an important way to strengthen and maintain the therapeutic alliance. It is important to acknowledge and respect a person's values and interests and recognize the medical team's own limitations of time or expertise to fully address their needs in a specific health area. Having resources and materials on hand for referrals to evidence-based IO information and care can support these efforts.

IO as a specialty area of oncology practice draws from many disciplines and health traditions, some of which may be rooted in the specific cultural traditions of people with cancer. Listening to peoples' questions about their healing traditions demonstrates cultural sensitivity that can also strengthen the therapeutic alliance. Although oncology team treatment discussions are rooted in western biomedicine, peoples' questions about integrative medicine may be rooted in cultural traditions. A useful perspective from medical anthropology speaks to the importance of recognizing the difference between having a disease (eg, cancer) and experiencing illness (the full experience of having a disease).[7] Most often, the interest of people with cancer in integrative medicine is about supporting well-being, not treating the disease.

Managing Symptoms

Symptom assessment using tools measuring patient-reported outcomes is the foundation of successful symptom management.[8] Understanding a person's symptoms can lead to thoughtful, evidence-based discussions regarding pharmacologic and nonpharmacologic therapeutic interventions. According to the recent ASCO guidelines regarding diet, exercise, and weight management, the Expert Panel identified the highest level of evidence for exercise, recommending oncology providers prescribe aerobic and resistance exercise during active treatment with curative intent to mitigate side effects of cancer treatment, such as fatigue, anxiety, and depression.[9]

Supporting Well-being

Supporting well-being in people with cancer during cancer treatment through lifestyle medicine is a fundamental aspect of IO. It addresses lifestyle factors such as diet/nutrition, exercise, stress reduction and mental health, social support, and sleep quality in the context of comorbidities and treatment phase in the cancer journey.[6] Health behavior strategies may include exercise counseling to reduce cancer-related fatigue, cognitive behavior therapy for insomnia to address sleep disturbances, or participation in mind-body practices (eg, mindfulness-based interventions, yoga therapy) to reduce anxiety. Partnering with mental health professions such as psychology, social work, or psychiatry can help patients with management of anxiety and/or mood disorders, whether preexisting or instigated by their cancer experience. Keep in mind that a history of mental health problems is a significant risk factor for recurrence of mood and anxiety disorders during cancer.

Treating Cancer

People with cancer, caregivers, and their families may have unrealistic expectations regarding the role of non–evidence-based therapies in the context of their cancer treatment. Pursuit of alternative, non–evidence-based therapies to treat cancer may cause harm, including but not limited to drug-herb interactions, direct organ toxicity, and financial toxicity.[10] Concerns regarding the use of alternative or non–evidence-based therapies include delays in access to conventional therapies that do offer opportunities for cure, potential for drug-herb interactions and/or organ toxicity (hepatotoxicity, nephrotoxicity, and bleeding risk), and financial toxicity.[10] Providing people with cancer and their families access to IO counseling can support evidence-based decision making regarding their cancer care, helping them preserve the therapeutic alliance with their oncology team and opportunities to improve treatment outcomes.

Evidence-based clinical practice guidelines for oncology care. One of the main questions oncology professionals may encounter is how to manage cancer and cancer

treatment–related symptoms, such as nausea, fatigue, pain, arthralgias, hot flashes, dry mouth, insomnia, depression, and anxiety. With awareness of the evidence supporting or not supporting certain IO approaches, oncology professionals can more competently lead discussions about managing common cancer-related symptoms. In addition to National Comprehensive Cancer Network guidelines, SIO and ASCO have developed several guidelines to help support clinicians working with people diagnosed with cancer. The oncology team should be familiar with two of the most recent SIO-ASCO guidelines and important clinical trials supporting them.

The first is the 2017 guideline on the use of integrative therapies during and after breast cancer treatment published by Greenlee et al,[11] which was subsequently endorsed by ASCO and published by Lyman et al[12] in 2018. This guideline summarizes the existing evidence and provides guidance on the use of integrative therapies for the management of symptoms and adverse effects, such as anxiety and stress, mood disorders, fatigue, pain, and sleep disturbance.[12] This guideline made the recommendation on the basis of the US Preventive Services Task Force (USPSTF) evidence grade definition, which defines grade A as "the USPSTF recommends the service as there is high certainty that the net benefit is substantial; grade B as USPSTF recommends the service as there is high certainty that the net benefit is moderate or there is moderate certainty that the net benefit is moderate to substantial; and grade C as the USPSTF recommends selectively offering or providing this service to individual patients based on professional judgement and patient preferences. There is at least moderate certainty that the net benefit is small."[13]

The key recommendations of this guideline include the use of music therapy, meditation, stress management, massage, and yoga for anxiety/stress reduction and depression/mood disorders, and acupressure and acupuncture for reducing chemotherapy-induced nausea and vomiting.[12] Although this guideline pertained only to women with breast cancer, with whom most of the research has been conducted to date, a growing volume of studies with people suffering from other types of cancer are consistently corroborating these recommendations. New joint SIO-ASCO guidelines on the use of integrative therapies for anxiety and depression across cancer types are in development and on track to be published in 2023.

The 2022 SIO-ASCO guideline on integrative medicine for pain management in oncology was developed by a group of international multidisciplinary experts and includes evidence-based recommendations for cancer pain management.[14] The following are the key recommendations (Table 1):

TABLE 1. Recommendations for the Use of Integrative Therapies During and After Breast Cancer Treatment

Symptom	Integrative Medicine Recommendations
Anxiety	Grade A: Meditation Grade B: Music, yoga, stress management
Depression and mood disorders	Grade A: MBSR meditation, relaxation Grade B: Music therapy
Fatigue	Grade C: Hypnosis
Quality of life	Grade A: Meditation Grade B: Yoga
Sleep disturbance	Grade C: Yoga

NOTE. Grade A: recommendation with high certainty; grade B: recommendation with moderate certainty; grade C: recommend selective offering. Adapted from the Integrative Medicine Breast Cancer guidelines.[11,12]
Abbreviation: MBSR, mindful based stress reduction.

1. Acupuncture should be offered to breast cancer survivors suffering from aromatase inhibitor–induced joint muscle pain.
2. Acupuncture may also be offered for general cancer pain or musculoskeletal pain.
3. Massage therapy may be offered to patients experiencing pain during palliative or hospice care.[14]

These recommendations stem from several large randomized controlled trials (RCTs). A phase III RCT randomly assigned 226 people with cancer suffering from aromatase inhibitor–induced joint muscle pain to three groups (acupuncture, sham acupuncture, and waitlist control); a greater proportion of people in the acupuncture group had clinically significant improvement in joint muscle pain compared with sham and control arms with minimal toxicities.[15] Durable treatment effects were reported at 6 months after random assignment.[16] Another large RCT with 360 people with cancer compared electroacupuncture with auricular (ear) acupuncture and usual care. It showed that electroacupuncture significantly reduced musculoskeletal pain by 1.9 points on a 0-10 numeric rating scale, auricular acupuncture reduced pain by 1.6 points, and usual care showed no significant improvement.[17] In another multicenter RCT, a total of 380 people with advanced cancer experiencing moderate-to-severe pain (90% were enrolled in hospice) were randomly assigned to massage or simple touch sessions (six 30-minute sessions over 2 weeks); massage was found to have immediate beneficial effect on pain reduction (mean difference, 0.90; $P = .001$) with no side effects.[18]

Tables 1 and 2 highlight the main evidence-based integrative medicine symptom management recommendations for people with cancer on the basis of the two above-mentioned guidelines.[11]

TABLE 2. Integrative Medicine Recommendations for Cancer-Related Pain Management

Symptom	Integrative Medicine Recommendations
Aromatase inhibitor–related join pain	Acupuncture (moderate strength)
	Yoga (weak strength)
General cancer pain or musculoskeletal pain	Acupuncture (moderate)
	Reflexology (moderate)
	Massage (moderate)
	Yoga (weak)
	Guided imagery with progressive muscle relaxation (weak)
Chemotherapy-induced peripheral neuropathy	Acupuncture (weak)
	Reflexology (weak)
Procedural pain	Hypnosis (moderate)
Surgical pain	Acupuncture (weak)
	Music (weak)
Pain during palliative care	Massage (moderate)

NOTE. Adapted from the Integrative Cancer Pain guidelines.[14]

TABLE 3. Questions to Ask About Each Dietary Supplement

Question	Rationale
What is the name of the supplement?	To identify the supplement
What brand is it?	To determine manufacturing quality of supplement
What dose are you taking?	To understand exposure and assess the effect
What is the duration of use?	To understand exposure and assess the effect
What are your goals of use?	To understand patient goals, beliefs, and priorities
Where did you get information about this supplement?	To understand if self-initiated vs. recommended by a health care professional

APPROPRIATE USE OF DIETARY SUPPLEMENTS DURING AND AFTER CANCER TREATMENT

People with cancer commonly use or are curious about using dietary supplements during and after cancer treatment: By some estimates, 64%-81% use vitamins and minerals; 26%-77% use multivitamins, and 24% use herbal and nonvitamin supplements.[19,20] In a 2014 ASCO Education Book, Harvie[21] reviewed phase II and phase III trials of nutrition supplements in cancer documenting potential benefits and proven harms. With few phase III trials, definitive data on the effects of dietary supplements are limited. Many trials investigating the effects of dietary supplements in patients on active cancer treatment are phase I and II trials. These gaps in knowledge make it challenging for providers to decide how best to counsel patients on the safe and appropriate use of dietary supplements.

SIO guidelines have also reviewed dietary supplements in published guidelines, and there are currently no strong recommendations to use dietary supplements for benefit. SIO guidelines have also recommended avoiding the use of some supplements for lack of benefit or possible harm. For example, acetyl-L-carnitine and guarana are not recommended for breast cancer treatment–related fatigue, and acetyl-L-carnitine is not recommended for prevention of chemotherapy-induced peripheral neuropathy because of potential harm.[11] Associations between any antioxidant use before and during chemotherapy treatment with cyclophosphamide, doxorubicin, and paclitaxel for breast cancer and increased hazard of recurrence also warrant caution.[22] Of note, high use of dietary supplements at the time of diagnosis has been associated with a decrease in treatment initiation.[23] Here, we provide our recommendations for best practices on dietary supplement use in oncology care.

Understand Goals of Dietary Supplement Use

It is important to understand a person's reasons for wanting to use a dietary supplement so that an appropriate conversation and informed decision-making process can follow. This is a conversation to have with people with cancer at multiple points during their care as they may change their dietary supplement use throughout their cancer treatment journey. It is useful to conduct a screening interview with people to determine detailed information on current or planned supplement use and to accurately document use in the medical record (eg, medication list). Table 3 lists specific information to ask about for each supplement.

Check for Interactions

Next, if possible, check the list of supplements for drug-supplement and supplement-supplement interactions for all supplements and drugs, not only oncology drugs. It is important to consider these interactions when initiating a new drug or clinically indicated supplement. Supplements should also be checked for potential harm as acetyl-L-carnitine may worsen chemotherapy-induced peripheral neuropathy.[24] Supplements may also have unwanted effects on disease states such as stimulation of hormone-sensitive cancers by products adulterated with testosterone or herbs that possess estrogenic properties.[25-28] It is important to again review for interactions when any new supplements are being considered or recommended. Table 4 shows a list of databases that can be useful when checking for interactions.

Efficacy

Once safety concerns are reviewed, it is important to understand why the person is interested in taking a supplement, review the evidence, and partner in making an

TABLE 4. Resources to Screen for Drug-Supplement and Supplement-Supplement Interactions

Name	Cost	URL

National Cancer Institute PDQ Cancer Information Summary: Integrative, Alternative, and Complementary Therapies	No cost	https://www.cancer.gov/publications/pdq/information-summaries/cam
National Institutes of Health Office of Dietary Supplements	No cost	https://ods.od.nih.gov
Natural Medicines	Access fee, some institutions have licenses	https://naturalmedicines.therapeuticresearch.com
UpToDate	Access fee, many institutions have licenses	https://www.uptodate.com
Consumer Labs	Access fee	https://www.consumerlab.com

NOTE. Ideally, clinicians can partner with their clinical pharmacy team who can screen for interactions, advise clinicians of potential concerns regarding the level of interaction (eg, none, minor, moderate, or major), and recommend a course of action. A small but growing number of oncology pharmacy groups have pharmacists identified who can do this work.

informed clinical recommendation regarding its use or discontinuation. Searching for peer-reviewed content using resources such as PubMed is a reliable approach to obtain information on the efficacy of specific supplements. Aggregate sources such as those listed in Table 4 can provide useful information more efficiently.

People with cancer may have an interest in supplements to help prevent or treat cancer treatment–related symptoms. As part of a therapeutic alliance, understanding these interests can help clinicians guide patients to consider other pharmacologic or nonpharmacologic evidence-based interventions for symptom relief.

Exploring patient goals in connection supplement use can include a discussion about nondietary supplement conventional or integrative medicine interventions that may benefit them.

Counseling People With Cancer About Safety and Efficacy

After gathering the necessary safety and efficacy information and understanding the person's values, goals, and beliefs, clinicians can use the pharmacists' recommendations, the available literature, and their clinical experience to counsel people on a recommended course of action. Follow-up dietary supplement counseling can be conducted through an additional appointment, phone call, electronic health record messages, or patient education documents. Documenting counseling recommendations in the medical record can be a helpful way to alert the health care team about these discussions and can also serve as a reminder for patients' future reference. Providers can build trust by sharing information about knowledge gaps and the levels of evidence (eg, preclinical, observational, human clinical trial, phase I, etc) that exist for specific dietary supplements (in a way that is accessible and easy to understand). In our clinical experience, people with cancer appreciate the process of making informed decisions about their dietary supplement use and are generally receptive to the information and recommendations provided to them.

Summary and Future Directions

Oncology patients frequently use dietary supplements at all points along the cancer care continuum. Patients may benefit from structured approaches to advising and managing the safe and appropriate use of dietary supplements. Further research is needed to fill in the large knowledge gaps in the areas of dietary supplement safety and efficacy.

MIND-BODY THERAPIES TO SUPPORT PEOPLE WITH CANCER

The definition of mind-body therapies (MBTs) is not clear-cut. The NCI defines a mind-body practice as "a health practice that combines mental focus, controlled breathing, and body movements to help relax the body and mind"[29] while the National Center for Complimentary and Integrative Health (NCCIH) describes MBTs as "a large and diverse group of procedures or techniques that are administered or taught by a trained practitioner or teacher."[30] There is agreement that practices including meditation, yoga, relaxation, hypnosis, and creative therapies are MBTs, but sometimes practices such as acupuncture, Reiki, and tai chi/qigong are also included. We will use an inclusive definition here. MBTs have been documented to improve emotional and psychological well-being in people with cancer and effectively address a variety of cancer-related symptoms, such as pain, fatigue, vasomotor symptoms, anxiety, depression, quality of life, and sleep. Brief summaries of the evidence for these symptoms are presented in the following sections.

Pain

Pain is a common and often persistent symptom after a cancer diagnosis.[31] MBTs have demonstrated efficacy in

different types of cancer-related pain. Meditation has been demonstrated to mediate pain via endogenous opioid pathways, which can be inhibited with naloxone.[32] Acupuncture has been recommended for joint pain related to aromatase inhibitor use, general cancer-related pain, and musculoskeletal pain.[14] Hypnosis was recommended for procedural pain.[14] As we have more fully entered the digital world with the COVID-19 global pandemic, mind-body therapies are being studied in virtual formats. Virtual-guided imagery is currently being studied as a pain treatment modality in the home setting.[33] Healing touch and music therapy received a USPSTF grade C, indicating that the evidence was equivocal.[13]

Fatigue

Individuals affected by cancer may experience fatigue at any point throughout their cancer journey. Although initially related to the disease, the side effects of therapy (eg, anemia) or to other factors (eg, poor sleep, deconditioning, or psychosocial stress) may also contribute to fatigue. Chronic persistent fatigue is present in about a third of persons with a history of breast cancer.[34] People describe fatigue as a weariness not relieved by rest and severely affecting one's quality of life.[35] In the 2017 guideline on the use of integrative therapies during and after breast cancer treatment, hypnosis and acupuncture received a grade C recommendation.[36,37] A more recent literature review recommended cognitive behavioral therapy plus hypnosis as recommendations for fatigue during active therapy and acupressure, mindfulness-based cognitive therapy, and qigong/Tai Chi Easy for post-treatment fatigue.[38]

Vasomotor Symptoms

Vasomotor symptoms or hot flashes may be a significant postcancer diagnosis symptom that is associated with changes in estrogens and androgens in the respective biological sex. These symptoms may be related to any treatment that affects hormonal function, which may include surgery, radiation, chemotherapy, and hormonal blockade therapy. The severity of the experience and the duration of the symptoms vary widely. Some people report vasomotor symptoms even years after the last menses.[39] Hot flashes are unpredictable and may be associated with palpitations, anxiety, poor sleep, and overall decreased quality of life. The 2017 breast cancer guideline gave a C grade to acupuncture on the basis of a large trial with electroacupuncture that demonstrated significant hot flash reduction in the electroacupuncture group compared with the sham and control groups.[40] One nonrandomized study in persons undergoing breast cancer surgery assessed hypnosis plus analgesic drugs compared with a single anesthesia treatment. Improvements in multiple postoperative factors including reduction of hot flashes were demonstrated.[41] A multinational study is currently investigating the role of acupuncture for hot flashes in persons with hormone receptor–positive breast cancer.[42]

Anxiety and Depression

Two of the most common and often inter-related symptoms that people with cancer experience, which are amenable to treatment with mind-body practices, are anxiety and depression. A systematic review of 210 studies reported a mean prevalence of clinical depression of 21.2% across cancer types,[43] and in 24 studies of people with advanced cancers, the rate of depressive disorder diagnoses was 24.6%.[44] Cross-culturally, a meta-analysis of 40 studies in 15 low- and middle-income countries reported a prevalence of 21% for major depression.[45] Within anxiety, a meta-analysis of 44 studies of over 50,000 cancer survivors reported a 17.9% prevalence of elevated anxiety symptoms.[46] Rates of anxiety and depression tend to be even higher around the time of diagnosis as the initial shock and implications of the disease are still being processed.[47]

The published 2017 SIO clinical practice guidelines on treating anxiety and depression in women with breast cancer include mindfulness meditation as a grade A recommendation for both symptoms.[20] Relaxation therapies also receive a grade A for relieving symptoms of depression and mood disturbance. Grade B therapies include yoga and music therapy for both anxiety and depression and massage for depression. Weaker recommendations for acupuncture and healing touch were made for anxiety and depression, respectively. These are summarized in Table 2, which also describes the key features of each of these mind-body therapies. Although this guideline pertained only to women with breast cancer, with whom most of the research has been conducted to date, a growing volume of studies with people suffering from other types of cancer are consistently corroborating these recommendations. New updated joint SIO-ASCO guidelines on integrative therapies for anxiety and depression across cancer types will be published later in 2023.

Quality of Life

Overall quality of life has been assessed as an outcome in many mind-body therapy studies. Tools used typically assess emotional, physical, functional, and social quality of life, as well as overall total quality of life across these domains. In this realm, mindfulness mediation again received a grade A recommendation, followed by yoga at grade B, and acupuncture, qigong, reflexology, and stress management as grade C therapies, like anxiety and depression.

Sleep

Sleep disturbance is another very common and burdensome symptom many people with cancer experience, with a prevalence of insomnia reported at nearly three times that of the general population, at 30%-50% of all people with cancer.[48] The research on integrative therapies for treating sleep disturbances and insomnia is less extensive than for the other symptoms covered, with only gentle yoga currently

being recommended in the breast cancer guidelines for improving sleep.[11] However, the gold standard treatment for insomnia is cognitive behavioral therapy for insomnia (CBT-I),[49] which is an adaptation of CBT specifically designed to address insomnia symptoms using behavioral methods, such as sleep monitoring, sleep restriction, relaxation training, and stimulus control, along with basic sleep hygiene. A noninferiority randomized controlled trial comparing a mindfulness-based intervention with CBT-I in people with cancer who were post-treatment diagnosed with full-blown insomnia showed quicker benefit for CBT-I immediately after treatment, but in a 3-month follow-up, the MBI was noninferior for improving both subjective and objective measures of sleep, as well as anxiety and depression.[50]

Choosing an MBT

Many different MBTs can be effective in treating the same symptom, as noted above. They have rarely been compared with one another in research studies, so making specific recommendations can be difficult. In general, whichever MBT a person is drawn to and feels they could participate in on a regular basis is likely to be beneficial. Typically, during treatment, less effortful therapies such as hypnosis, relaxation, and imagery can help alleviate symptoms; going into long-term survivorship, therapies that require more individual self-management and effort such as mediation and yoga may be preferred.

How to Find an Integrative Clinician

NCI-Designated Cancer Centers increasingly include IO care.[3] Reaching out to a nearby cancer center may provide you with potential contacts and referrals for your patients and for additional CME opportunities. The SIO offers a public directory on its website (https://integrativeonc.org/public-directory). The University of Arizona offers a directory of clinicians who have completed the fellowship in integrative medicine (https://integrativemedicine.arizona.edu/alumni.html). The American Board of Physician Specialties provides a search function on their website to identify physicians boarded in integrative medicine (https://www.abpsus.org/for-patients/).

CONCLUSION

IO incorporates evidence-based integrative therapies into cancer care using a person-centered approach and can effectively manage some cancer symptoms and cancer treatment–related side effects. Oncology health care professionals should be aware of the importance of this growing field, be well-versed in the evidence behind it, and willing to discuss integrative therapy options to help improve the quality of life of people with cancer and develop and maintain trust and rapport. Future research is needed to continue to expand the field to understand the mechanisms, efficacy, effectiveness, and implement ability of IO approaches to reduce cancer symptom and side effects.
