Speculative bubble

Short-selling ban

## ABSTRACT

We develop a model of temporary short-selling bans by extending the infinite-horizon model of Scheinkman and Xiong (2003). Our model predicts that a temporary short-selling ban leads to a speculative bubble that is the highest at the beginning of the ban and gradually converges to zero. Examining the 2008 short-selling ban in the U.S., we find evidence consistent with the model's predictions. The innovation of our empirical design is to use the financial segments of non-banned stocks as a control group for the banned financial stocks. Our results are robust across different test specifications and different samples of stocks.

## 1. Introduction

Regulators around the world have increasingly resorted to short-selling bans as a market-stabilizing tool in times of crises. On September 18, 2008, the U.S. Securities and Exchange Commission (SEC) issued an emergency order to temporarily ban the short selling of nearly all financial stocks. Many countries followed suit and imposed similar bans during the global financial crisis (Beber and Pagano, 2013). In August 2011, at the height of eurozone sovereign debt crisis, four European countries (i.e., Belgium, France, Italy, and Spain) imposed short-selling bans on financial stocks. More recently, in the wake of the COVID-19 pandemic, market regulators in many European and Asian countries once again restricted short sales.

Short selling in general, and short-sale restrictions in particular, have been the subject of extensive academic research both before and after 2008. While there is general consensus that short-selling bans are detrimental to market liquidity and price discovery (e.g., Battalio and Schultz (2011), Beber and Pagano (2013), and Boehmer et al. (2013)), there is considerable disagreement about their impact on stock prices. Miller (1977) argues that, in the presence of divergence of opinion, short-sale constraints will lead to overvaluation because pessimistic investors are kept out of the market and prices only reflect the views of optimistic investors. Diamond and Verrecchia (1987) develop a rational expectations model and show that short-sale constraints will not lead to overvaluation because rational agents take into account the fact that investors with negative information are sidelined by short-sale constraints. Bai et al. (2006) show that, when investors are risk averse, short-sale constraints increase the risk perceived (and the expected return required) by uninformed investors, which in turn leads to lower prices. Therefore, in theory, short-selling bans could have a positive, negative, or no effect on prices.

The empirical evidence on the price effect of short-selling bans is equally mixed. Autore et al. (2011) examine the 2008 short-selling ban of financial stocks in the U.S. and find that, consistent with Miller (1977), banned stocks exhibit positive abnormal

returns at the initiation of the ban. Battalio et al. (2012), however, conclude that the 2008 ban failed to support the price of financial stocks. Beber and Pagano (2013) show that the 2008–2009 short selling bans are not associated with better stock price performance in most countries except the U.S. Boehmer et al. (2013) find that the 2008 ban in the U.S. leads to higher prices for banned financial stocks relative to a matching sample of unbanned stocks, but only for large stocks, not small stocks. Moreover, the price effect is non-existent for stocks added to the ban list after the initial announcement. Both Beber and Pagano (2013) and Boehmer et al. (2013) attribute the price inflation of the banned stocks in the U.S. to the confounding news about the Troubled Asset Relief Program (TARP) instead of the short-selling ban. Finally, Harris et al. (2013) use a factor-model approach and estimate that the 2008 short-selling ban in the U.S. led to a price inflation of 10%–12% in the banned stocks after controlling for a TARP factor.

In this paper, we study the price effect of temporary short-selling bans both theoretically and empirically. We first build a continuous-time asset pricing model with heterogeneous beliefs and temporary short-selling bans by extending the work of Scheinkman and Xiong (2003). The key prediction of our model is that a temporary short-selling ban leads to a price inflation that is the highest at the beginning of the ban and gradually converges to zero at the end of the ban. We test this prediction by revisiting the 2008 short-selling ban of financial stocks in the U.S. The innovation of our empirical design is to use the financial segments of non-banned non-financial stocks as a control group for the banned financial stocks. We find evidence consistent with our model's prediction.

The setting of our model is similar to that of Scheinkman and Xiong (2003). There is a single risky asset with limited supply. The dividend for the risky asset is driven by a fundamental variable, which is not observable. There are two noisy signals about the fundamental variable and there are two groups of risk-neutral agents. The signals are public information. However, the two groups of agents interpret the signals differently. Specifically, each group of agents overestimate the informativeness of a different signal. This overconfidence leads to heterogeneous beliefs and different valuations.

As in Scheinkman and Xiong (2003), owning a share of the risky asset today provides an opportunity to profit from future overvaluation by the other group of agents, i.e., by selling the risky asset to the other group of agents. This resale option has value because short selling is prohibited. As a consequence, the demand price of the agents depends not only on their assessment of the fundamentals but also on the value of this resale option. Scheinkman and Xiong (2003) call the resale option value a “bubble”. In this paper, we also refer to it as overpricing, overvaluation, or price inflation.

Scheinkman and Xiong (2003) study an infinite horizon problem where short-selling is banned permanently. As explained by Scheinkman and Xiong (2003, p. 1195), “the infinite horizon problem is stationary, greatly reducing the mathematical difficulty”. In practice, short-selling bans are almost always temporary in nature—the duration of the 2008–2009 short-selling bans ranges from 19 days in Canada and the U.S. to 277 days in Ireland and Luxembourg (Beber and Pagano, 2013). Departing from Scheinkman and Xiong (2003), we study a finite-horizon problem, which allows us to examine the effect of temporary short-selling bans. In this case, the resale option value, i.e., the magnitude of the overvaluation, also depends on the remaining life of the ban. While the analytical solutions to an infinite-horizon problem can be obtained by solving an ordinary differential equation, one has to solve a partial differential equation for the finite horizon problem, which is more challenging.

We obtain a closed-form solution for the resale option value by using the Laplace transform and Kummer functions. This solution enables us to study the dynamics of the overpricing caused by a temporary short-selling ban for the first time. Our model predicts that the size of the initial overpricing is increasing in the length of the ban and the degree of overconfidence, and decreasing in the level of interest rate and the speed of the mean reversion in the fundamentals. More importantly, our model predicts that a temporary short-selling ban leads to an overpricing that is the highest at the beginning of the ban and gradually shrinks to zero at the end of the ban.

We test the above prediction by examining the 2008 short-selling ban of financial stocks in the U.S. As stated earlier, an extensive literature has examined the price effect of the 2008 ban with mixed findings. The key challenge in this literature, as argued by Battalio and Schultz (2012, p. 3), is that “since almost all financial stocks were targeted by the ban, it is difficult (if not impossible) to find an appropriate benchmark against which to evaluate their returns”. Most prior studies employ benchmarks consisting mainly of non-financial stocks. For example, Boehmer et al. (2013) construct a matched control sample based on listing exchange, market capitalization, trading volume, and whether or not listing options exist. Battalio et al. (2012) and Harris et al. (2013) compare the return of banned stocks with an index extracted from all non-banned stocks, the vast majority of which are non-financial. Beber and Pagano (2013) attempt to use both of these methods. Autore et al. (2011) calculate the abnormal return for banned stocks relative to the entire market or the Fama and French (1993) three-factor model.

Comparing financial stocks with a matched sample of non-financial stocks is likely sufficient for studying the ban's effect on liquidity and price discovery, but is not ideal for examining the price effect. Abnormal returns estimated using this approach may be attributed to differences between financial and non-financial stocks instead of the effects of the ban. In particular, the fundamentals of financial stocks are likely to be quite different from those of non-financial stocks during the 2007–2009 financial crisis. Beber and Pagano (2013, p. 355) recognize this limitation and acknowledge that their approach “has the drawback of leaving only financials in the treatment group and only non-financials in the control group”.

We overcome this challenge by using the financial segments of the non-banned non-financial stocks as a control group for the banned financial stocks. We observe that many non-banned non-financial firms have financial segments. We identify these financial segments by using the Compustat Business Segment data and define financial ratio ( $f$ ) as the fraction of a firm's total sales attributed to financial segments. We then decompose the daily stock returns of these non-financial firms into a portion that is driven by non-financial segments and a portion driven by financial segments. We use these implied returns driven by the financial segments as the benchmark returns to the banned financial stocks.

When we use all non-financial stocks as the control group, which is similar to what previous studies have done, we find that banned financial stocks experience a significant price inflation at the beginning of the short-selling ban, and this price inflation persists well after the ban is lifted. Based on this evidence, one might conclude that it is not the short-selling ban, but rather the contemporaneous news about TARP, that causes the price inflation in financial stocks. By contrast, when using the financial segments of the non-financial stocks as the control group, we find significant evidence of price inflation at the onset of the ban, and this initial overvaluation reverts at the end of the ban. Namely, both the ban and the price inflation are temporary. This convergence result is new in the literature, contrary to the existing findings (see, for example, [Harris et al. \(2013\)](#)), and consistent with the prediction of our model.

We perform several robustness tests and additional analyses. First, we construct several alternative measures of  $f$ , including a measure based on the regressions of stock returns. Our results are generally robust. Second, we include in our sample not only stocks on the initial ban list but also stocks subsequently added to the list and find our results to be robust. Third, we perform a placebo test by repeating our main analysis for four alternative sample periods and do not find evidence of price inflation in banned financial stocks.<sup>1</sup>

We make two contributions to the short selling literature. The first is to develop a model of temporary short-selling bans. Prior studies examine either static models or dynamic models with permanent short-selling bans. These models offer great insights into the price effect of short-selling bans in general. However, existing theories do not explicitly model temporary short-selling bans; as such, they cannot predict how prices evolve from the start of the ban to the end of the ban. Despite the technical challenges involved in solving a finite-horizon dynamic model, we obtain a closed-form solution for the overpricing caused by the short-selling ban. This explicit solution allows us to study the dynamics of the price effect associated with temporary short-selling bans for the first time.

Our second contribution is to offer an alternative empirical design to study the price effect of the 2008 short-selling ban. In contrast to previous studies, which use all non-financial stocks or a matching sample of these stocks as the control group for the banned financial stocks, we use the financial segments of non-financial stocks as the control group. These financial segments share the same features as financial firms except that they are not subject to the ban. Although our approach is not perfect – one might argue that the financial segments of non-financial stocks are different from the banned financial stocks – our control is new, and arguably better than those in the literature for the purpose of examining the price effect of the 2008 ban.

Our paper is closely related to an extensive theoretical and empirical literature on the asset pricing implications of differences of opinions and short-sale constraint ([Hong and Stein \(2003\)](#), [Hong et al. \(2006\)](#)). [Chen et al. \(2002\)](#) argue that in the presence of short-sales constraints and investor disagreement, a stock's breadth of ownership should positively predict its future returns. They find evidence consistent with this prediction. [Cen et al. \(2013\)](#) extend [Chen et al. \(2002\)](#) and show that the breadth of ownership-stock return relation varies with investor sentiment. [Diether et al. \(2002\)](#) show that dispersion of analyst forecasts, a proxy for differences of opinion, is negatively related to the cross-section of stock returns. [Cen et al. \(2017\)](#) propose an alternative disagreement proxy by using the change in the standard deviation of analyst forecasts. [Gallmeyer and Hollifield \(2008\)](#) show that the price effect of a market-wide short-sale constraint in a dynamic economy with heterogeneous beliefs depends critically on the optimistic investors' intertemporal elasticity of substitution. [Chabakauri \(2015\)](#) shows that portfolio constraints have significant effects on asset prices. In particular, short-sale constraints decrease asset return volatility. [Simsek \(2021\)](#) reviews the literature on financial speculation driven by belief disagreements. He shows that with short-selling constraints, speculation can generate overvaluation and speculative bubbles, and that leverage can substantially inflate speculative bubbles.

Our paper is also related to an extensive literature showing that short-selling activities predict the cross-section of stock returns. [Desai et al. \(2002\)](#) and [Asquith et al. \(2005\)](#) present evidence that monthly short interest is negatively related to future stock returns. [Boehmer et al. \(2008\)](#) and [Diether et al. \(2009\)](#) examine daily shorting flows and show that heavily shorted stocks underperform lightly shorted stocks. [Engelberg et al. \(2012\)](#), [Jones et al. \(2016\)](#), [Kelley and Tetlock \(2016\)](#), [McLean et al. \(2020\)](#), and [Wang et al. \(2020\)](#) also present evidence that short sellers are informed.

The rest of the paper proceeds as follows. Section 2 presents our model of temporary short-selling bans. Section 3 describes our data and presents our main results. Section 4 presents the results for several robustness tests and additional analyses. Section 5 concludes.

## 2. The model

In this section, we develop a continuous-time asset pricing model with heterogeneous beliefs and temporary short-selling bans. Our setting is similar to that of [Scheinkman and Xiong \(2003\)](#) except that they study an infinite-horizon problem, whereas we analyze a finite-horizon problem. The equilibrium price becomes time dependent in the finite period setting. Section 2.1 presents the information structure and beliefs. Section 2.2 solves for the equilibrium price. Section 2.3 characterizes the dynamics of the price.

### 2.1. Information structure and beliefs

There is a single risky asset with limited supply. The stock pays dividends during  $[0, T]$ . The dividend process is driven by a fundamental variable  $f_t$  and noise  $dZ_t^D$ . Thus,

<sup>1</sup> We thank the editor and two anonymous referees for suggesting these analyses.

$$dD_t = f_t dt + \sigma_D dZ_t^D, \quad (1)$$

where  $Z^D$  denotes a standard Brownian motion and  $\sigma_D$  denotes a constant volatility parameter.

The fundamental variable  $f_t$  is not observable, and it follows a mean-reverting process, as follows:

$$df_t = -\lambda(f_t - \bar{f})dt + \sigma_f dZ_t^f, \quad (2)$$

where  $\lambda$  denotes the mean reversion parameter and  $\bar{f}$  denotes the long-run mean of  $f$ .

The risky asset is in finite supply and we normalize the total supply to one. There are two groups of risk-neutral agents, Group A and Group B, trading the risky asset during  $[0, T]$ . Following [Scheinkman and Xiong \(2003\)](#), we assume that the number of agents in each group is infinitely large and that short selling of the risky asset is prohibited. To value future dividends, we assume that agents discount all future cash flows using the interest rate  $r$  and that each group has infinite total wealth.

All agents observe two noisy signals about  $f$ :

$$ds_t^A = f_t dt + \sigma_s dZ_t^A \quad (3)$$

and

$$ds_t^B = f_t dt + \sigma_s dZ_t^B. \quad (4)$$

We assume that all four processes,  $Z^D$ ,  $Z^f$ ,  $Z^A$ , and  $Z^B$ , are independent with each other. All agents know the structure (the stochastic differential equations and the parameters) but cannot observe  $f_t$ . They try to infer  $f$  from the dividend  $D$  and the two signals  $s_A$  and  $s_B$ .

The agents are not perfectly rational when interpreting the signals. Specifically, agents in Group A (B) think of  $s_A$  ( $s_B$ ) as their own signal and overestimate its informativeness. The behavioral finance literature characterizes such agents as being overconfident. In the meantime, agents in Group A (B) correctly estimate the informativeness of the other signal  $s_B$  ( $s_A$ ).

We operationalize overconfidence in the same way as in [Scheinkman and Xiong \(2003\)](#). Specifically, agents in Group A (B) believe that  $dZ^A$  ( $dZ^B$ ) is correlated with  $dZ^f$  with a correlation parameter  $\phi$  ( $0 < \phi < 1$ ). The agents in Group A therefore believe,

$$\begin{cases} ds_t^A = f_t dt + \sigma_s \phi dZ_t^f + \sigma_s \sqrt{1 - \phi^2} dZ_t^A \\ ds_t^B = f_t dt + \sigma_s dZ_t^B. \end{cases} \quad (5)$$

The agents in Group A optimally filter the signals  $D_t$ ,  $s_t^A$ , and  $s_t^B$  to form their beliefs about the fundamentals  $f_t$ . Specifically, based on the optimal filtering theory, the conditional belief about  $f_t$  by investors in Group A is Gaussian with mean  $\hat{f}_t^A$  and variance  $\gamma$ , where  $\gamma$  is a constant:

$$\gamma \equiv \frac{-[\lambda + (\phi\sigma_f/\sigma_s)] + \sqrt{[\lambda + (\phi\sigma_f/\sigma_s)]^2 + (1 - \phi^2)[(\sigma_f^2/\sigma_D^2) + (2\sigma_f^2/\sigma_s^2)]}}{(1/\sigma_D^2) + (2/\sigma_s^2)}. \quad (6)$$

It is easy to show that  $\gamma$  is decreasing in  $\phi$ . This justifies associating the parameter  $\phi$  to overconfidence. Following [Scheinkman and Xiong \(2003\)](#), we refer to  $\hat{f}_t^A$  as the belief of Group A investors. This conditional mean satisfies:

$$d\hat{f}_t^A = -\lambda(\hat{f}_t^A - \bar{f})dt + \frac{\phi\sigma_s\sigma_f + \gamma}{\sigma_s^2}(ds_t^A - \hat{f}_t^A dt) + \frac{\gamma}{\sigma_s^2}(ds_t^B - \hat{f}_t^A dt) + \frac{\gamma}{\sigma_D^2}(dD - \hat{f}_t^A dt). \quad (7)$$

The conditional belief is mean-reverting, as shown in the first term in Eq. (7). The other three terms correspond to surprises due to the dividend process and the two signals. Comparing the two terms associated with signal  $s^A$  and signal  $s^B$ , we can see that Group A investors respond more to surprises in signal  $s^A$  than in signal  $s^B$  due to overconfidence.

Investors in Group B are overconfident about signal  $s_t^B$  and form their belief  $\hat{f}_t^B$  in a similar way:

$$d\hat{f}_t^B = -\lambda(\hat{f}_t^B - \bar{f})dt + \frac{\gamma}{\sigma_s^2}(ds_t^A - \hat{f}_t^B dt) + \frac{\phi\sigma_s\sigma_f + \gamma}{\sigma_s^2}(ds_t^B - \hat{f}_t^B dt) + \frac{\gamma}{\sigma_D^2}(dD - \hat{f}_t^B dt). \quad (8)$$

The difference of beliefs  $g^A = \hat{f}_t^B - \hat{f}_t^A$  satisfies a simple stochastic differential equation (SDE) based on Proposition 1 in [Scheinkman and Xiong \(2003\)](#):

$$dg^A = -\rho g^A dt + \sigma dW_g^A, \quad (9)$$

where  $\rho$  and  $\sigma$  are constant:

$$\rho = \sqrt{(\lambda + \phi\frac{\sigma_f}{\sigma_s})^2 + (1 - \phi^2)\sigma_f^2(\frac{2}{\sigma_s^2} + \frac{1}{\sigma_D^2})} \quad (10)$$

$$\sigma = \sqrt{2\phi\sigma_f}. \quad (11)$$

We refer to  $\sigma$  as the volatility of the difference in beliefs. It is increasing in  $\phi$  (the degree of overconfidence) and  $\sigma_f$  (the volatility of the fundamentals).

In a similar fashion, we can show that, for agents in Group B,  $g^B = \hat{f}^A - \hat{f}^B$  satisfies:

$$dg^B = -\rho g^B dt + \sigma dW_g^B, \quad (12)$$

where  $\rho$  and  $\sigma$  are identical to those shown above.

## 2.2. Equilibrium price

The agents who are more optimistic about the future payoffs will be willing to pay a higher price for the risky asset and consequently hold the entire supply. For tractability, we assume there is no trading cost.<sup>2</sup> In this case, trading occurs when the beliefs of the two groups of agents differ. The short-sale ban, a finite supply of shares, and the infinite number of agents in each group guarantee that the equilibrium price will be equal to the reservation price of the more optimistic group of agents.

At time  $t \in [0, T]$ , Group A investors' expectation of the discounted future dividends is.<sup>3</sup>

$$\mathbf{E}_t^A \left[ \int_t^T e^{-r(s-t)} dD_s \right] = \frac{\bar{f}}{r} (1 - e^{-r(T-t)}) + \frac{\hat{f}_t^A - \bar{f}}{r + \lambda} (1 - e^{-(r+\lambda)(T-t)}). \quad (13)$$

If there are only Group A investors in the market, then the price of the stock will be equal to this expectation. However, there are also Group B investors in the market with a different expectation of future dividends:

$$\mathbf{E}_t^B \left[ \int_t^T e^{-r(s-t)} dD_s \right] = \frac{\bar{f}}{r} (1 - e^{-r(T-t)}) + \frac{\hat{f}_t^B - \bar{f}}{r + \lambda} (1 - e^{-(r+\lambda)(T-t)}). \quad (14)$$

Because short-selling is banned, pessimistic investors with a lower expectation will sit out of the market. Optimistic investors with a higher expectation will be the owners of the stock and set the price. It is possible that the pessimistic investors will become optimistic in the future and want to buy the stock from the current owner. Thus, when setting the price, the current owner will also consider the value of the resale option. So, the price is the current owner's expectation of future dividends plus the value of a resale option:

$$p_t^o = p(\hat{f}_t^o, g_t^o, t) = \frac{\bar{f}}{r} (1 - e^{-r(T-t)}) + \frac{\hat{f}_t^o - \bar{f}}{r + \lambda} (1 - e^{-(r+\lambda)(T-t)}) + q(g_t^o, t), \quad (15)$$

where the superscript "o" denotes the group of agents who currently own the asset. The value of the resale option  $q(g_t^o, t)$  depends on the difference of beliefs between the two groups, i.e.,  $g^o = \hat{f}^{\hat{o}} - \hat{f}^{\bar{o}}$ , where "o" denotes the other group of agents who do not own the stock at this moment  $t$ .

The owner determines an optimal time  $\tau$  to sell the stock to maximize the dividends collected and the capital gain:

$$p_t^o = \sup_{t \leq \tau \leq T} \mathbf{E}_t^o \left[ \int_t^\tau e^{-r(s-t)} dD_s + e^{-r(\tau-t)} p_\tau^{\bar{o}} \right]. \quad (16)$$

At the end of the trading period, the price is  $p_T^o = 0$  because there are no more dividends to be distributed and there are no more chances to profit from re-selling the stock. Further, the price is required to be smooth (continuously differentiable). This technical requirement guarantees the uniqueness of the solution.

Expressing  $p_t^o$  and  $p_\tau^{\bar{o}}$  in the optimal decision Eq. (16) by the candidate equilibrium price Eq. (15), one can derive the equation for the resale option. Together with the boundary condition and technical requirement, we have:

$$\begin{cases} q(g_t^o, t) = \sup_{t \leq \tau \leq T} \mathbf{E}_t^o \{ e^{-r(\tau-t)} [ \frac{g_t^o}{r+\lambda} (1 - e^{-(r+\lambda)(T-\tau)}) + q(g_\tau^{\bar{o}}, \tau) ] \} \\ q(g_t^o, T) = 0 \\ q \text{ is smooth.} \end{cases} \quad (17)$$

This is an optimal execution problem. Let  $x = g_t^o = \hat{f}_t^{\hat{o}} - \hat{f}_t^{\bar{o}}$  be the current belief difference between the two groups of investors.

**Lemma 1.** *The stock owner will wait if  $x < 0$  and sell if  $x \geq 0$ .*

When  $x < 0$ , the owner is more optimistic and chooses not to sell. If there is a positive trading cost, investors will choose to wait if  $x < k$ , where  $k$  is a positive number that depends on the trading cost and remaining time until  $T$ . However, if there is no trading cost, as is assumed here, trading will occur whenever the beliefs cross. Thus, the owner will wait if  $x < 0$  and sell if  $x \geq 0$ . The proof of Lemma 1 is in Appendix A.2.

<sup>2</sup> Scheinkman and Xiong (2003) assume positive trading costs in their model because of their desire to study trading volume and volatility. We focus more on the price effect of the short-selling ban. Scheinkman and Xiong (2003) show that the speculative bubble still exists when there is no trading cost.

<sup>3</sup> For brevity, we provide a detailed proof of Eq. (13) in Appendix A.1

The discounted value of this resale option  $e^{-rt}q(g_t^o, t)$  is a martingale to the current stock holder. Based on Ito's lemma and the evolution equation for  $g_t^o$ , we have:

$$\frac{1}{2}\sigma_g^2 q_{xx} - \rho x q_x + q_t - r q = 0, \quad x < 0. \quad (18)$$

If the current belief difference is non-negative,  $x \geq 0$ , the stock owner is more pessimistic and chooses to sell right now. Then the optimal execution time is equal to current time  $\tau = t$  and the value of the resale option is:

$$q(x, t) = \frac{x}{r + \lambda}(1 - e^{-(r+\lambda)(T-t)}) + q(-x, t), \quad x \geq 0. \quad (19)$$

The requirement of  $q(x, t)$  being smooth means  $q(x, t)$  and  $q_x(x, t)$  are continuous when  $x$  crosses 0.

Thus, the optimal execution problem is transformed to a PDE for  $x < 0$  and  $0 \leq t \leq T$ :<sup>4</sup>

$$\begin{cases} \frac{1}{2}\sigma_g^2 q_{xx} - \rho x q_x + q_t - r q = 0 \\ q(x, T) = 0 \\ q_x(0, t) = \frac{1}{2(r+\lambda)}(1 - e^{-(r+\lambda)(T-t)}). \end{cases} \quad (20)$$

If the second order derivative term in Eq. (20) was  $\frac{1}{2}\sigma_g^2 x^2 q_{xx}$  instead of  $\frac{1}{2}\sigma_g^2 q_{xx}$ , it would be the Black–Scholes equation and could be solved by transforming it into a diffusion equation. Without the  $x^2$  term, the problem is much more challenging to solve. Also, if the boundary condition were the Dirac delta function, physicists could solve it by performing a Fourier transform. The more complicated boundary condition further increases the difficulty in solving this PDE.

By performing a Laplace transform on the equation and using the integral form of the Kummer function, we are able to obtain a solution to the above PDE, as shown in Theorem 1.

**Theorem 1.** *The solution to Eq. (20) is:*<sup>5</sup>

$$u(x, t) = \frac{\sigma}{4(r + \lambda)\sqrt{\pi\rho}} \int_{N(t)}^{\infty} e^{-\frac{\rho}{\sigma^2}x^2 y} y^{\frac{r-2\rho}{2\rho}} (1 + y)^{-\frac{r+\rho}{2\rho}} [1 - e^{-(r+\lambda)(T-t-M(y))}] dy, \quad (21)$$

where  $N(t) = \frac{e^{-2\rho(T-t)}}{1 - e^{-2\rho(T-t)}}$ ,  $M(y) = \frac{1}{2\rho} \ln(1 + \frac{1}{y})$ ,  $x < 0$ , and  $0 \leq t \leq T$ . The speculative bubble, i.e., the value of the resale option, is then:

$$q(x, t) = \begin{cases} \frac{x}{r+\lambda}(1 - e^{-(r+\lambda)(T-t)}) + u(-x, t) & x \geq 0 \\ u(x, t) & x < 0. \end{cases} \quad (22)$$

### 2.3. Dynamics of the price during the short-selling ban

We analyze a finite-horizon problem to study how prices evolve during the life of the short-selling ban. Based on Theorem 1, we show that the speculative bubble shrinks during the ban and vanishes at the end of the ban, as shown in Theorem 2.

**Theorem 2.** *The speculative bubble  $q(x, t)$  is decreasing in  $t$  and equals 0 when  $t = T$ .*

This is the main testable prediction of our model. This is also where our model differs from Scheinkman and Xiong (2003). In Scheinkman and Xiong (2003), the speculative bubble is not dependent on  $t$ . The proof of Theorem 2 is in Appendix A.5.

We note that in Theorem 1 the magnitude of the speculative bubble  $q(x, t)$  is determined by time  $t$  and the current difference of beliefs from the stock owners' perspective,  $x$ . Averaging the stochastic term  $x$  in  $q(x, t)$  can lead to the mean magnitude of the bubble  $\bar{q}(t)$ , which only depends on time.

The difference of beliefs from Group A investors' perspective  $g^A = \hat{f}^B - \hat{f}^A$  satisfies a simple SDE based on Eq. (12), as follows:

$$dg^A = -\rho g^A dt + \sigma dW_g. \quad (23)$$

The stationary distribution of this process is normal,  $N(0, \eta^2)$ , where  $\eta^2 = \frac{\sigma^2}{2\rho}$ . The same distribution applies to  $g^B$  since  $g^B = \hat{f}^A - \hat{f}^B = -g^A$ . When Group A investors hold the stock,  $\hat{f}^B < \hat{f}^A$ , thus  $x = g^A < 0$ . When Group B investors hold the stock,  $\hat{f}^A < \hat{f}^B$ , thus  $x = g^B = -g^A < 0$ . So  $x$  is always less than or equal to zero with a stationary distribution that doubles the left half of the normal distribution  $N(0, \eta^2)$ :

$$w(x)dx = 2 \cdot \frac{1}{\eta\sqrt{2\pi}} \cdot e^{-\frac{x^2}{2\eta^2}} dx \quad x < 0. \quad (24)$$

<sup>4</sup> The detailed proof is in Appendix A.3.

<sup>5</sup> The detailed proof of Theorem 1 is in Appendix A.4.

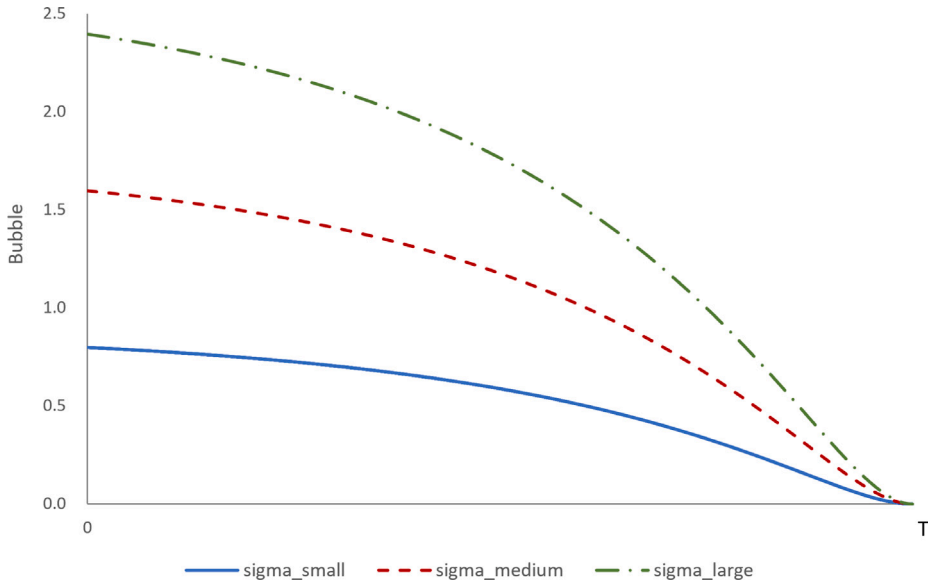

Fig. 1. Dynamics of the bubble and volatility of disagreement.

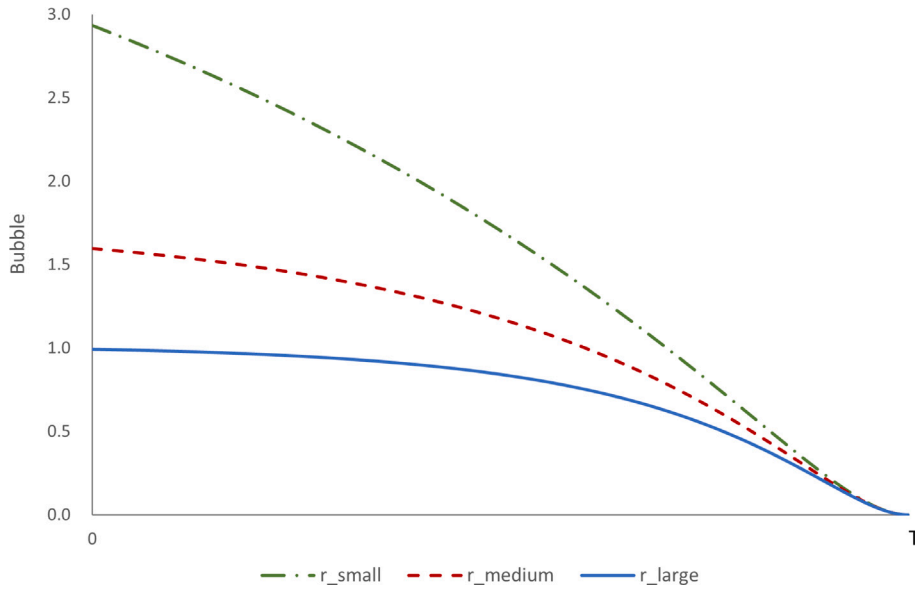

Fig. 2. Dynamics of the bubble and interest rate.

**Theorem 3.** Averaging the speculative bubble  $q(x, t)$  in Eq. (22) with the stationary distribution  $w(x)dx$  in Eq. (24) leads to the mean magnitude of the bubble.<sup>6</sup>

$$\bar{q}(t) = \frac{\sigma\sqrt{\rho}}{2\lambda\sqrt{\pi}} \left[ \frac{1}{r}(1 - e^{-r(T-t)}) - \frac{1}{r+\lambda}(1 - e^{-(r+\lambda)(T-t)}) \right]. \quad (25)$$

Based on Theorem 3, we can see that the size of the average bubble increases linearly in  $\sigma$ , the volatility of the disagreement process. It also increases linearly in  $\sqrt{\rho}$ , the square root of the mean reversion coefficient of the disagreement process, and decreases in the mean reversion coefficient of the fundamentals. It is also clear that the average bubble size is increasing in  $T$ , and decreasing in  $t$  and  $r$ .

<sup>6</sup> The proof for Theorem 3 is in Appendix A.6

Fig. 3. Dynamics of the bubble and mean-reversion coefficient of fundamental.

Fig. 4. Dynamics of the bubble and mean-reversion coefficient of disagreement.

In Figs. 1–4, we plot the evolution of the bubble over time for different values of the parameters. The  $x$ -axis shows the time starting at 0 and ending at  $T$ . The  $y$ -axis shows the average overvaluation caused by the ban. Fig. 1 shows the relation between the bubble and the volatility of disagreement. When the disagreement process is more volatile, it is easier to observe extreme disagreement and trading occurs more frequently, which leads to a higher speculative bubble. Fig. 2 shows that increasing interest rate  $r$  will make the size of the bubble smaller because it decreases the present value of the future resale price, which makes investors less willing to speculate. In Fig. 3, as we increase the mean-reversion coefficient of the true fundamental of the stock  $\lambda$ , the size of the bubble will decrease, because it makes the fundamental converge to the long-term mean at a faster speed, which decreases the excess dividends that optimistic investors expect to collect. In Fig. 4, the size of the bubble increases with  $\rho$ , the mean-reversion in

the disagreement between the two groups of investors. A larger  $\rho$  means that the investors' beliefs are more likely to cross, and thus increases the value of the resale option.

We derive [Theorem 4](#) to show the dynamics of the average bubble over time.

**Theorem 4.** *The average bubble  $\bar{q}(t)$  is decreasing in  $t$  and vanishes at the end of the short-selling ban. Let  $\tau^* = \frac{1}{\lambda} \ln(1 + \frac{\lambda}{r})$ ; then the inflection point of  $\bar{q}(t)$  is at  $t^* = T - \tau^*$ . When  $t < t^*$ ,  $\bar{q}(t)$  is concave; when  $t^* < t < T$ ,  $\bar{q}(t)$  is convex. At the inflection point, the bubble has the highest decreasing speed  $\frac{d\bar{q}(t)}{dt} \Big|_{t=t^*} = \frac{-\sigma\sqrt{\rho}}{2(r+\lambda)\sqrt{\pi}} \left(\frac{r}{r+\lambda}\right)^{\frac{r}{\lambda}}$ .<sup>7</sup>*

Based on [Theorem 4](#), the remaining time when the bubble crosses an inflection point is  $\tau^* = \frac{1}{\lambda} \ln(1 + \frac{\lambda}{r})$ . When the remaining time  $T - t$  is bigger than  $\tau^*$ , the curve of the bubble is concave. When it is very close to the end of the ban (i.e.,  $T - t$  is smaller than  $\tau^*$ ), the curve is convex. As  $r \rightarrow +\infty$ ,  $\tau^* \rightarrow 0$ . This means the curve is always concave and the rate of the decrease is highest at the end of the ban. As  $r \rightarrow 0$ ,  $\tau^* \rightarrow +\infty$ . The whole curve will be convex. As  $\lambda \rightarrow +\infty$ ,  $\tau^* \rightarrow 0$  and as  $\lambda \rightarrow 0$ ,  $\tau^* \rightarrow \frac{1}{r}$ .  $r$  and  $\lambda$  together determine the position of the inflection point and thus the shape of the bubble curve.

Fixing the other parameters, increasing  $T$  can be realized by moving the  $t = 0$  point to the left (extend the curve to the left such that it takes time  $T$  to vanish). A larger  $T$  leads to a higher initial bubble; however, the bubble will not go to infinity. Indeed, as  $T \rightarrow +\infty$ ,  $\bar{p}(t) \equiv \bar{p}_{T=\infty} = \frac{\sigma\sqrt{\rho}}{2(r+\lambda)\sqrt{\pi}}$ . That is, an infinite ban leads to a constant average bubble. This result is consistent with [Scheinkman and Xiong \(2003\)](#).

### 3. Empirical analysis

The central prediction of our model is that a temporary short-selling ban leads to price inflation (i.e., bubble) that is the highest at the beginning of the ban and shrinks to zero at the end of the ban. We test this prediction by examining the 2008 short-selling ban of financial stocks in the U.S. [Section 3.1](#) discusses the timeline of the 2008 ban. [Section 3.2](#) describes our data, sample, and methodology. [Section 3.3](#) presents the empirical results.

#### 3.1. Timeline of the 2008 ban

Beginning in the summer of 2008, the SEC implemented a series of short-selling restrictions. In July 2008, the SEC issued an emergency order restricting naked short selling in 19 large financial stocks. After the emergency order expired in mid-August, the SEC announced a permanent ban on September 17 on naked shorting in all U.S. stocks effective the next day. On September 18, the SEC issued another emergency order, temporarily banning short sales in 797 financial stocks. The initial order covered ten business days, and was set to expire on October 2, 2008. On September 21, the SEC announced that all decisions about banned stocks would be delegated to the individual exchanges. From September 22 and October 7, an additional 148 stocks were added to the ban list by the exchanges. On October 2, 2008, at the end of the initial 10-day ban, the SEC extended the ban to October 17, 2008 or three days after the passage of the TARP bill, whichever is earlier. The TARP bill was passed on October 3 and the short-sale ban ended at mid-night on October 8. As of October 9, short selling was again permitted (except that naked shorting was still banned).

The 2008 short-selling ban is contemporaneous with news about TARP, which was a response to the market turmoil following the Lehman Brothers collapse. On September 18, Treasury secretary Henry Paulson announced the intention to work on a market stabilization plan, i.e., to create TARP. On September 29, the plan was rejected by Congress, sending the Dow Jones Industrial Average down 778 points. Two days later on October 1, 2008, the Senate passed the Emergency Economic Stabilization Act (EESA), the bill that authorized TARP by a vote of 74 to 25. On October 3, 2008, the House of Representatives passed the EESA by a vote of 263 to 171 and President George W. Bush signed the EESA into law.<sup>8</sup> On October 13 and 14, the U.S. Treasury announced a standardized program to purchase equity in a broad array of financial institutions and the Capital Purchase Program (CPP), respectively.

#### 3.2. Data, sample, and methods

##### 3.2.1. Data and sample

After the SEC banned short sales in 797 financial stocks, the individual exchanges then added an additional 148 stocks to the ban list from September 22 and October 7 of 2008. Our empirical analysis includes only stocks on the initial ban list.<sup>9</sup> This choice is motivated by two factors. First, the initial list is arguably a cleaner sample because the short-selling ban announced on September 18, 2008 was a surprise. In comparison, the subsequent additions to the ban list were likely partially anticipated. Second, the main testable prediction of our model is that a short-selling ban leads to a price inflation that shrinks during the life of the ban. Examining banned stocks on the initial list allows us to study a more uniform window and hence more cleanly test our model's predictions.

<sup>7</sup> The proof for [Theorem 4](#) is in [Appendix A.7](#).

<sup>8</sup> <http://www.treasury.gov/initiatives/financial-stability/reports/Pages/TARP-Tracker.aspx>.

<sup>9</sup> The 148 stocks added to the ban list after September 18 are completely removed from our main analysis. They serve neither as banned stocks nor as control stocks. We show in [Section 4.3](#) that including these 148 stocks in our sample does not qualitatively change our results.

**Table 1**  
Business segments and financial factor.

| Company name             | SIC  | Banned | Segment                                  | Segment SIC  | Sales (\$ million) |
|--------------------------|------|--------|--|--------------|--------------------|
| Cohen & Steers INC       | 6282 | Yes    | Investment Banking                       | 6282         | 185.83             |
| CASS Information Systems | 7389 | No     | Banking Services<br>Information Services | 6022<br>7389 | 15.16<br>76.57     |

We obtain stock price and return data from the Center for Research in Security Prices (CRSP). We restrict our sample to common stocks (with a share code of 10 or 11) traded on NYSE, NASDAQ, and AMEX. Our sample period is from August 19 (one month before the ban starts) to November 7, 2008 (one month after the ban ends). We require that all stocks have full price and return data during these 58 trading days. We obtain the business segments and the corresponding SIC codes from Compustat. We merge the CRSP and Compustat data by using the CRSP-Compustat link file. We also require that all stocks have business segment data. Our final sample includes 3,330 stocks.

### 3.2.2. Methodology

We use the financial segments of non-financial firms as the benchmark to evaluate the price effect of the ban. Each stock in the 2008 Compustat business segment database has an SIC code to identify its principal business. In addition, each stock has one or more business segments. For each segment, there is a segment-level SIC code and a record of segment sales and assets. We identify financial segments based on this segment-level SIC code (those with an SIC code between 6000 and 6999). We remove a number of segments that are created to record eliminations due to accounting issues. These segments usually have names such as "Elimination," "Other," or "Adjustment." The assets or sales are sometimes negative for these segments.

Table 1 illustrates the business segments of two example companies: Cohen and Steers Inc. and CASS Information Systems. Cohen and Steers's principal SIC code is 6282, which is investment banking. The company has only one business segment, which not surprisingly also has an SIC code of 6282. The segment, as well as the company as a whole, generated \$185.83 million in sales in 2008. Cohen and Steers is a financial firm and was on the initial short-selling ban list.

In comparison, CASS Information Systems has two business segments. The first segment is in banking services with an SIC code of 6022. This segment generated \$15.16 million in sales in 2008. The second segment is in information systems and has an SIC code of 7389. This segment generated \$76.57 million in sales in 2008. Because the principal business of CASS Information Systems is in information systems, its principal SIC code is 7389. As a result, the company was not banned from short selling in 2008.

For each company in our sample, we calculate its financial factor  $f$  as the financial segment's contribution to total sales, as follows:

$$f = \frac{\sum_{fin} Sales}{\sum_{all} Sales}, \quad (26)$$

where  $fin$  is the index of all financial segments.<sup>10</sup>

For CASS Information Systems, we have:

$$f = \frac{15.16}{15.16 + 76.57} = 16.53\% \quad (27)$$

A stock with financial factor  $f = 1$  is a purely financial firm, like Cohen and Steers. If a company has no financial segment, then  $f = 0$ . A company with  $0 < f < 1$  has both financial and non-financial segments.

During the entire 58 trading days, which includes 22 trading days before the ban, 14 days during the ban, and 22 days after the ban, the banned stocks have a ban indicator of  $b_{it} = 1$  and the unbanned stocks have  $b_{it} = 0$ . The stocks with  $b_{it} = 1$  before or after the ban serve as the placebo group: the banned and non-banned financial stocks should behave more similarly before the ban than during the ban.

On each trading day  $t$ , we assume that the return of each stock can be potentially explained by four factor returns: the factor return of banned financial stocks  $R_t^{BF}$ , the factor return of non-banned financial stocks  $R_t^{NF}$ , the factor return of banned non-financial stocks  $R_t^{BN}$ , and the factor return of non-banned non-financial stocks  $R_t^{NN}$ . Specifically, we decompose the return of each stock on each day into these factor returns based on the ban indicator and the financial factor, as follows:

$$r_{it} = f_i(b_{it}R_t^{BF} + (1 - b_{it})R_t^{NF}) + (1 - f_i)(b_{it}R_t^{BN} + (1 - b_{it})R_t^{NN}) + \epsilon_{it}. \quad (28)$$

In the example shown in Table 1, Cohen and Steers is a pure financial company. Thus its financial factor is  $f_i = 1$ . Since the stock is banned from short-selling, its ban indicator is  $b_{it} = 1$ , for all  $t$ . Substituting these into Eq. (28), we have:

$$r_{it} = R_t^{BF} + \epsilon_{it}. \quad (29)$$

As a purely financial company that is banned from short-selling, Cohen and Steers' daily return is assumed to be driven by the factor return of banned financial stocks.

<sup>10</sup> In robustness tests, we calculate alternative  $f$  based on free cash flows, operating profits, and total assets instead of sales.

Because 16.53% of the business of CASS Information Systems is financial, its financial factor is  $f_j = 0.1653$ . The stock is not banned from short-selling, so its ban indicator is  $b_{jt} = 0$ , for all  $t$ . Substituting these into Eq. (28), we have:

$$r_{jt} = 0.1653 \cdot R_t^{NF} + 0.8347 \cdot R_t^{NN} + \epsilon_{jt}. \quad (30)$$

As a non-banned stock with 16.53% of its business being financial and 83.47% of its business being non-financial, its daily return is assumed to be driven by the factor return of non-banned financial stocks and the factor return of the non-banned non-financial stocks.

We estimate the four factors,  $R_t^{BF}$ ,  $R_t^{NF}$ ,  $R_t^{BN}$ , and  $R_t^{NN}$ , from Eq. (28) by running a cross-sectional regression of stock returns on the coefficients of these four factors each day. For example, the four coefficients are 1, 0, 0, and 0 for Cohen and Steers, and 0, 0.1653, 0, and, 0.8347 for CASS Information Systems. To measure the price effect of the ban, we take the difference between  $R_t^{BF}$  and  $R_t^{NF}$ .

### 3.3. Empirical results

Before presenting the results for our methodology, i.e., using the financial segments of non-financial stocks as a control group, we first show what happens when we use all nonbanned stocks as a control group. This approach is similar to those employed in previous studies. Doing so establishes a baseline to which we can compare our results.

We begin by constructing equal-weighted portfolios of all banned stocks and non-banned stocks, respectively. We then compute the cumulative returns of each portfolio for the period from August 19 to November 7. We plot the time series of these cumulative returns in Fig. 5. We can see that the performance of banned stocks began diverging from non-banned stocks in early September and this divergence widened significantly when the short-selling ban was announced, indicating a significant price inflation of banned stocks when compared to the non-banned stocks. This overvaluation, however, persisted not only during the short-selling ban but also well after the ban was lifted. Based on this result, one would likely reach the same conclusion as [Beber and Pagano \(2013\)](#) and [Boehmer et al. \(2013\)](#), i.e., the observed price inflation of the banned stocks is unlikely to be driven by the short-selling ban and more likely caused by the contemporaneous news about TARP.

We now present the results from our approach. As stated earlier, we estimate the four factors,  $R_t^{BF}$ ,  $R_t^{NF}$ ,  $R_t^{BN}$ , and  $R_t^{NN}$ , from Eq. (28). We then use the difference between  $R_t^{BF}$  and  $R_t^{NF}$  to measure the price effect of the ban. Fig. 6 shows the cumulative returns of  $R_t^{BF}$  and the cumulative returns of  $R_t^{NF}$ .<sup>11</sup> The two returns are reasonably close to each other before the ban. On the announcement day and the subsequent day, the two returns significantly diverged. Specifically,  $R_t^{BF}$  significantly outperformed  $R_t^{NF}$  on those two days. This divergence, however, shrank during the ban and then disappeared at the end of the ban. This finding is in stark contrast to what we find in Fig. 5.

Table 2 presents the day-by-day results of  $R_t^{BF}$  and  $R_t^{NF}$ . We find that  $R_t^{BF}$  significantly outperformed  $R_t^{NF}$  by 3.84% on September 18, 2008, the announcement day of the short-selling ban, and by 6.14% on September 19, 2008, the first effective day of the ban. Both of these return differences are statistically significant.  $R_t^{BF}$  then significantly underperformed  $R_t^{NF}$  by 1.95% on October 8, 2008, the last day of the short-selling ban, and by 6.97% on October 9, 2008, the first day without the ban. Overall, the initial price inflation is completely reversed by the end of the ban, supporting our model's prediction.

Any test of the price effect of the 2008 short-selling ban is potentially confounded by the contemporaneous news about TARP. In our setting, we acknowledge that TARP potentially benefited the banned financial stocks more than the financial segments of the non-financial stocks. However, TARP is not characterized by a single announcement, but rather represented by a series of news, some of which are negative. The detailed Capital Purchase Program was not announced until October 14, after the short-selling ban was lifted. There is some ambiguity about the valuation effect of TARP ([Bayazitova and Shivdasani, 2012](#)), especially during the short-selling ban, before the details of the program became known. Indeed, [Bayazitova and Shivdasani \(2012\)](#) suggest that the TARP announcement on October 14 was largely unanticipated by the market. Although we cannot completely rule out the impact of TARP, our convergence result strongly suggests that the price inflation of the banned financial stocks at the beginning of the ban cannot be entirely due to TARP. If the initial price inflation is driven by TARP and this effect is permanent, then such overvaluation should persist after the ban. In other words, the fact that the initial overpricing shrinks to zero at the end of the ban suggests that our results are more likely due to the ban itself rather than TARP.

## 4. Robustness tests and additional analyses

In this section, we present the results for several robustness tests and additional analyses. For brevity, we present the detailed results for these analyses in the Internet Appendix.

### 4.1. $f$ based on alternative accounting data

In our main analysis, we calculate the financial ratio  $f$  as the fraction of sales attributed to financial segments. We consider three alternative definitions of the financial ratio. Specifically, instead of sales, we use free cash flows, operating profits, and total assets to construct the financial factor and repeat our analysis. Overall, we obtain very similar results to those presented in Fig. 6. We continue to find that the price inflation is the highest at the beginning of the ban and gradually converges to zero at the end of the ban.

<sup>11</sup> We note that the difference between the cumulative  $R_t^{BF}$  and cumulative  $R_t^{NF}$  captures the level of price inflation. In comparison, the difference between  $R_t^{BF}$  and  $R_t^{NF}$  (reported in Table 2) captures the change in price inflation.

**Fig. 5. Cumulative returns of banned vs. non-banned stocks.** This figure shows the cumulative returns of banned stocks and the cumulative returns of the non-banned stocks. The vertical lines indicate the first day and the last day of the ban.

**Fig. 6. The price effect of the 2008 short-selling ban on financial stocks.** This figure shows the cumulative returns of  $R^{BF}$  and the cumulative returns of  $R^{NF}$  estimated from Eq. (28). The vertical lines indicate the first day and the last day of the ban. The shaded area indicates the 95% confidence interval of the cumulative returns of  $R^{BF}$ .

**Table 2**  
The price effect of the 2008 short-selling ban on financial stocks.

This table presents the daily returns  $R^{BF}$  and  $R^{NF}$  estimated from Eq. (28).  $R^{BF}$  is the factor return for banned financial stocks.  $R^{NF}$  is the factor return for non-banned financial stocks.

\* Significance at the 5% level.

\*\* Significance at the 1% level.

#### 4.2. Return-based financial ratio $f$

In our main analyses, we construct the financial ratio  $f$  based on segment-level accounting data. In this robustness test, we construct  $f$  by regressing daily stock returns on the aggregate returns of financial industry. Specifically, we estimate the following regression equation using the past six months' stock returns:  $R_{it} = aR_t^f + bR_t^{nf} + e_{it}$ , where  $R_t^f$  is the daily returns of the financial industry and  $R_t^{nf}$  is the average returns of the non-financial industries. We use the estimated loading on the financial industry return as a proxy for the financial ratio  $f$ .

We construct the aggregate financial industry returns by calculating the value-weighted returns of all financial stocks. We classify financial stocks in two ways. In the first approach, we define financial stocks based on the Fama–French 12 industry classifications. In the second approach, we define financial stocks as those stocks with only financial segments. The main difference between these two approaches is that the former includes stocks with non-financial segments, while the latter includes only pure financial firms. Overall, the results (especially the results for the second approach) generally follow a similar pattern to that of our main analysis.

#### 4.3. Subsequent additions to the ban list

On September 18, the SEC issued another emergency order, temporarily banning short sales of 797 financial stocks. From September 22 and October 7, an additional 148 stocks were added to the ban list by the exchanges. In the main analyses, we include only the stocks on the initial ban list for two reasons. First, the initial list is arguably a cleaner sample because the short-selling ban announced on September 18, 2008 was a surprise. In comparison, the additions to the ban list during subsequent days may be partially anticipated. Second, the main testable prediction of our model is that a short-selling ban leads to a price inflation that shrinks during the life of the ban period. Examining banned stocks on the initial list allows us to study a more uniform window and hence more cleanly test the prediction of our model.

Nonetheless, there is potentially important information in the 148 stocks that were excluded from our analysis. In this subsection, we perform a robustness test by adding these stocks to the sample to see whether the main results are robust. We repeat our main analysis and find that our results are qualitatively unchanged.

#### 4.4. A placebo test

In this section, we run a placebo test by repeating our main analysis for four alternative sample periods. Two of these periods are chosen to be exactly one year before and one year after the actual ban period. The other two 60-day periods are chosen randomly during 2007–2009. The only requirement is that they cannot overlap with the actual sample period. Overall, we do not find evidence of price inflation in banned financial stocks during these four periods.

#### 4.5. Future research

According to SEC's initial announcement On September 19 of 2008, the short-selling ban will terminate at 11:59 p.m. ET on Oct. 2, 2008. However, they also stated that "The Commission may extend the order beyond 10 business days if it deems an extension necessary in the public interest and for the protection of investors, but will not extend the order for more than 30 calendar days in total duration".<sup>12</sup> On October 1 of 2008, the SEC issued another statement to extend the ban. According to the second announcement, the ban would be extended to allow time for completion of work on the anticipated passage of legislation. The actual duration of the 2008 short-selling ban was therefore longer than the initially announced.

In our model, we assume that the length of the ban is fixed. However, as the SEC mentioned in their statement,<sup>13</sup> "The steps the Commission has taken are designed to ensure the continued smooth operation of orderly markets" and "The Commission staff will continue to monitor the impact of the rules regarding short selling". If investors realize the possibility that the ban may last longer, their expectation of the resale-option value would change, which in turn would change the price of the stocks and the size of the speculative bubble. Therefore, a potentially interesting extension of our model is to allow the length of the ban  $T$  to be a random variable.

Furthermore, the length of the ban could even be endogenous. Since the goal of regulators is to provide price support for the stock market, the realized level of price inflation could be an important input in their decision to extend the ban. Recognizing this, investors might revise their belief on  $T$  during the ban according to regulators' decision rule. Compared to the fixed  $T$  model, the model with a random and endogenous  $T$  should offer more insights into the relation between the temporary ban and the dynamics of price bubbles. We believe this is an interesting and important avenue for future research.

## 5. Conclusion

Short-selling bans have become a regular and predictable response from regulators when facing market crises. In this paper, we study the price effect of temporary short-selling bans both theoretically and empirically. We first build a continuous-time asset pricing model with heterogeneous beliefs and temporary short-selling bans by extending the work of Scheinkman and Xiong (2003). We obtain a closed-form solution for the overpricing caused by the short-selling ban. This solution enables us to study the dynamics of the overpricing caused by a temporary short-selling ban for the first time. Our model predicts that the size of the initial overpricing is increasing in the length of the ban and the degree of overconfidence, and decreasing in the level of interest rate and the speed of the mean reversion in the fundamentals. More importantly, our model predicts that a temporary short-selling ban leads to an overpricing that is the highest at the beginning of the ban and gradually converges to zero at the end of the ban.

We test this prediction by revisiting the 2008 short-selling ban of financial stocks in the U.S. Previous studies compare banned financial stocks to non-banned non-financial stocks. Such comparison cannot account for the fundamental difference between financial and non-financial stocks during the 2007–2009 financial crisis. The innovation of our empirical design is to use the financial segments of non-banned stocks as a control group for the banned financial stocks. We find evidence consistent with our model's prediction. Because the initial overpricing shrinks to zero at the end of the ban, our results are unlikely to be driven entirely by the TARP effect. An interesting avenue for future research is to examine a random-horizon model where the length of the ban is random and endogenous.

## Appendix

### A.1. Proof of Eq. (13)-investors' expectation of the discounted future dividends

**Proof.** Since the dividend process is driven by a fundamental variable  $f_t$  and noise  $dZ_t^D$ , where  $Z^D$  is a standard Brownian motion, we have  $dD_s = f_s ds$ . Therefore, investor A's expectation of the discounted future dividends  $E_t^A \left[ \int_t^T e^{-r(s-t)} dD_s \right]$  can be written as  $E_t^A \left[ \int_t^T e^{-r(s-t)} f_s ds \right]$ . Recall the belief of investor A (i.e., Eq. (7) of the paper):

$$d\hat{f}^A = -\lambda(\hat{f}^A - \bar{f})dt + \frac{\phi\sigma_s\sigma_f + \gamma}{\sigma_s^2}(ds^A - \hat{f}^A dt) + \frac{\gamma}{\sigma_s^2}(ds^B - \hat{f}^A dt) + \frac{\gamma}{\sigma_D^2}(dD - \hat{f}^A dt). \quad (\text{A.1})$$

<sup>12</sup> <https://www.sec.gov/news/press/2008/2008-211.htm>.

<sup>13</sup> <https://www.sec.gov/news/press/2008/2008-235.htm>.

According to Eq. (5),  $ds^A = f_t dt + \sigma_s \phi dZ_t^f + \sigma_s \sqrt{1 - \phi^2} dZ_t^A$ , therefore,  $ds^A - \hat{f}^A dt = \sigma_s \phi dZ_t^f + \sigma_s \sqrt{1 - \phi^2} dZ_t^A$ . Since  $Z^f$  is a standard Brownian motion and  $Z^A$  is also a standard Brownian motion,  $\mathbf{E}_t^A [ds^A - \hat{f}^A dt] = 0$ . For the same reason, we can prove that  $\mathbf{E}_t^A [ds^B - \hat{f}^A dt] = 0$ , and  $\mathbf{E}_t^A [dD - \hat{f}^A dt] = 0$ .

Therefore, the expected value of Eq. (7) can be written as  $\mathbf{E}_t^A [d\hat{f}^A] = -\lambda(\hat{f}^A - \bar{f})dt$ .

The solution to this ODE is  $\hat{f}_s^A = \bar{f} + Ce^{-\lambda(s-t)}$ . The constant  $C$  can be determined by letting  $s = t$ . Thus,  $C = \hat{f}_t^A - \bar{f}$ . Thus,  $\hat{f}_s^A = \bar{f} + (\hat{f}_t^A - \bar{f})e^{-\lambda(s-t)}$ .

$$\begin{aligned} \mathbf{E}_t^A \left[ \int_t^T e^{-r(s-t)} dD_s \right] &= \mathbf{E}_t^A \left[ \int_t^T e^{-r(s-t)} f_s ds \right] \\ &= \int_t^T e^{-r(s-t)} [\bar{f} + (\hat{f}_t^A - \bar{f})e^{-\lambda(s-t)}] ds \\ &= \frac{\bar{f}}{r} (1 - e^{-r(T-t)}) + \frac{\hat{f}_t^A - \bar{f}}{r + \lambda} (1 - e^{-(r+\lambda)(T-t)}). \end{aligned} \quad (\text{A.2})$$

When  $T$  goes to infinity, the above equation will become  $\frac{\bar{f}}{r} + \frac{\hat{f}_t^A - \bar{f}}{r + \lambda}$ , which is the same as the investor's expected present value of future dividends in Scheinkman and Xiong (2003) (see Eq. (12) of their paper). ■

## A.2. Proof of Lemma 1

### Proof.

Let  $k \geq 0$  be the minimum difference of opinions to generate a trade.

If the current belief difference is greater than  $k$ , the stock owner chooses to sell right now. Then the optimal execution time is equal to current time  $\tau = t$  and the optimal value of the right-hand side is realized in the first equation of (17).

$$q(x, t) = \frac{x}{r + \lambda} (1 - e^{-(r+\lambda)(T-t)}) + q(-x, t), \quad x \geq k. \quad (\text{A.3})$$

The requirement of  $q(x, t)$  being smooth in Eq. (17) means  $q(x, t)$  and  $q_x(x, t)$  are continuous when  $x$  crosses  $k$ .

Since  $\lim_{x \rightarrow k^+} q(x, t) = \lim_{x \rightarrow k^+} [\frac{x}{r + \lambda} (1 - e^{-(r+\lambda)(T-t)}) + q(-x, t)] = \frac{k}{r + \lambda} (1 - e^{-(r+\lambda)(T-t)}) + q(-k, t)$  and  $\lim_{x \rightarrow k^-} q(x, t) = q(k, t)$ , the continuation of  $q(x, t)$  implies:

$$k \cdot \frac{1}{r + \lambda} (1 - e^{-(r+\lambda)(T-t)}) = q(k, t) - q(-k, t). \quad (\text{A.4})$$

Since  $\lim_{x \rightarrow k^+} q_x(x, t) = \lim_{x \rightarrow k^+} [\frac{1}{r + \lambda} (1 - e^{-(r+\lambda)(T-t)}) - q_x(-x, t)] = \frac{1}{r + \lambda} (1 - e^{-(r+\lambda)(T-t)}) - q_x(-k, t)$  and  $\lim_{x \rightarrow 0^-} q_x(x, t) = q_x(k, t)$ , the continuation of  $q_x(x, t)$  implies:

$$\frac{1}{(r + \lambda)} (1 - e^{-(r+\lambda)(T-t)}) = q_x(k, t) + q_x(-k, t). \quad (\text{A.5})$$

substituting (A.5) into (A.4), we know that  $k$  must satisfy:

$$k \cdot [q_x(k, t) + q_x(-k, t)] - q(k, t) + q(-k, t) = 0. \quad (\text{A.6})$$

Let  $l(k) = k \cdot [q_x(k, t) + q_x(-k, t)] - q(k, t) + q(-k, t)$ , we have  $l(0) = 0$ . Thus, 0 is one solution of Eq. (A.6).

We also have  $l'(k) = k \cdot [q_{xx}(k, t) - q_{xx}(-k, t)]$ . Similar to Lemma 2 in Scheinkman and Xiong (2003), we know that  $q_{xx}(x, t)$  is increasing. When  $k > 0$ , we have  $k > -k$ . This means  $q_{xx}(k, t) - q_{xx}(-k, t) > 0$ . Thus,  $l'(k) > 0$ . When  $k < 0$ , we have  $k < -k$ . This means  $q_{xx}(k, t) - q_{xx}(-k, t) < 0$ . Thus, we also have  $l'(k) > 0$ . So, we know that  $l'(k) > 0$  for all  $k \neq 0$ . This means 0 is the only solution of Eq. (A.6). We have proved that the owner will wait if  $x < 0$  and sell if  $x \geq 0$ . ■

## A.3. Transforming the optimal execution problem (17) to a PDE

### Proof. Since

$$\lim_{x \rightarrow 0^+} q(x, t) = \lim_{x \rightarrow 0^+} [\frac{x}{r + \lambda} (1 - e^{-(r+\lambda)(T-t)}) + q(-x, t)] = q(0, t) \quad (\text{A.7})$$

and

$$\lim_{x \rightarrow 0^-} q(x, t) = q(0, t), \quad (\text{A.8})$$

the continuation of  $q(x, t)$  is satisfied automatically. Since

$$\lim_{x \rightarrow 0^+} q_x(x, t) = \lim_{x \rightarrow 0^+} [\frac{1}{r + \lambda} (1 - e^{-(r+\lambda)(T-t)}) - q_x(-x, t)] = \frac{1}{r + \lambda} (1 - e^{-(r+\lambda)(T-t)}) - q_x(0, t) \quad (\text{A.9})$$

and

$$\lim_{x \rightarrow 0^-} q_x(x, t) = q_x(0, t), \quad (\text{A.10})$$

the continuation of  $q_x(x, t)$  means:

$$q_x(0, t) = \frac{1}{2(r + \lambda)} (1 - e^{-(r+\lambda)(T-t)}). \quad \blacksquare \quad (\text{A.11})$$

A.4. Proof of Theorem 1

**Proof.** The PDE to be solved is:

$$\begin{cases} \frac{1}{2}\sigma^2 q_{xx} - \rho x q_x + q_t - r q = 0 \\ q(x, T) = 0 \\ q_x(0, t) = \frac{1}{2(r+\lambda)}(1 - e^{-(r+\lambda)(T-t)}), \end{cases} \quad (\text{A.12})$$

where  $x < 0$  and  $0 \leq t \leq T$ . The boundary condition is at the end of the ban when  $t = T$ . By setting  $\tau = T - t$ , one can make the boundary condition lie at the beginning of the new time  $\tau$ . Let  $l(x, \tau) = q(x, T - \tau)$ , then  $l(x, \tau)$  satisfies:

$$\begin{cases} \frac{1}{2}\sigma^2 l_{xx} - \rho x l_x - l_\tau - r l = 0 & \text{PDE} \\ l(x, 0) = 0 & \text{Initial condition} \\ l_x(0, \tau) = \frac{1}{2(r+\lambda)}(1 - e^{-(r+\lambda)\tau}) & \text{Boundary condition,} \end{cases} \quad (\text{A.13})$$

where  $x < 0$  and  $0 \leq \tau$ . The PDE and the boundary condition is well-defined for all  $\tau > T$ , thus we can solve it for all  $\tau \geq 0$  and then pick the  $0 \leq \tau \leq T$  part.

Consider performing a Laplace transform on this PDE. The Laplace transform of a function  $f(\tau)$  is  $F(s) = \mathcal{L}[f(\tau)] = \int_0^\infty e^{-s\tau} f(\tau) d\tau$ . Let  $L(x, s) = \mathcal{L}[l(x, \tau)]$ . Performing a Laplace transform on the PDE of  $l(x, \tau)$  and using the following properties of the Laplace transform

$$\mathcal{L}[af(\tau) + bg(\tau)] = aF(s) + bG(s) \quad (\text{A.14})$$

$$\mathcal{L}[f'(\tau)] = sF(s) - f(0), \quad (\text{A.15})$$

we get:

$$\frac{1}{2}\sigma_g^2 L_{xx} - \rho x L_x - [sL(x, s) - l(x, 0)] - rL = 0. \quad (\text{A.16})$$

Using the initial condition  $l(x, 0) = 0$ , we have:

$$\frac{1}{2}\sigma_g^2 L_{xx} - \rho x L_x - (s+r)L = 0. \quad (\text{A.17})$$

For a fixed  $s$ , this is an ODE of  $x$ . This ODE has a class of solutions of the form:

$$L(x, s) = \beta(s)h(x, s), \quad (\text{A.18})$$

where  $\beta(s)$  is an arbitrary function of  $s$  and

$$h(x, s) = U\left(\frac{r+s}{2\rho}, \frac{1}{2}, \frac{\rho}{\sigma^2}x^2\right), \quad (\text{A.19})$$

where  $U(\cdot)$  is the Kummer U function:<sup>14</sup>

$$U(a, b, z) = \frac{1}{\Gamma(a)} \int_0^\infty e^{-zy} y^{a-1} (1+y)^{b-a-1} dy. \quad (\text{A.20})$$

We can use the boundary condition to pin down the function  $\beta(s)$ . Using linearity and the following property of Laplace transform

$$\mathcal{L}[e^{a\tau}] = \frac{1}{s-a}, \quad (\text{A.21})$$

we have the Laplace transform of the boundary condition:

$$L_x(0, s) = \mathcal{L}[l_x(0, \tau)] = \mathcal{L}\left[\frac{1}{2(r+\lambda)}(1 - e^{-(r+\lambda)\tau})\right] = \frac{1}{2(r+\lambda)}\left(\frac{1}{s} - \frac{1}{s+r+\lambda}\right). \quad (\text{A.22})$$

On the other hand, we know  $L_x(0, s) = \beta(s)h_x(0, s)$  and  $h_x(0, s) = \frac{\pi\sqrt{\rho}}{\sigma\Gamma(\frac{r+s}{2\rho})\Gamma(\frac{3}{2})}$ . Thus, we can solve  $\beta(s)$ :

$$\beta(s) = \frac{\sigma\Gamma(\frac{r+s}{2\rho})\Gamma(\frac{3}{2})}{2(r+\lambda)\pi\sqrt{\rho}}\left(\frac{1}{s} - \frac{1}{s+r+\lambda}\right). \quad (\text{A.23})$$

Based on Eqs. (A.18), (A.19), (A.20), and (A.23), we have:

$$L(x, s) = \int_0^\infty A(x, y) \left(\frac{1}{s} - \frac{1}{s+r+\lambda}\right) e^{-M(y)s} dy. \quad (\text{A.24})$$

<sup>14</sup> Scheinkman and Xiong (2003) use this Kummer U function to express the solution of a similar ODE. They use the sum of series for the U function. We use the integration form of the Kummer U function because it makes the inverse Laplace transform possible.

where  $A(x, y) = \frac{\sigma}{4(r+\lambda)\sqrt{\pi\rho}} e^{-\frac{\rho}{\sigma^2}x^2y} y^{\frac{r-2\rho}{2\rho}} (1+y)^{-\frac{r+\rho}{2\rho}}$  and  $M(y) = \frac{1}{2\rho} \ln(1 + \frac{1}{y})$ .

With the following property of the inverse Laplace transform, we can get  $l(x, \tau)$  from  $L(x, s)$ :

$$\mathcal{L}^{-1}[\frac{1}{s+a} e^{-bs}] = u(\tau - b)e^{-a(\tau-b)}, \tag{A.25}$$

where  $u(x)$  is the unit step function: if  $x > 0$ ,  $u(x) = 1$ ; if  $x < 0$ ,  $u(x) = 0$ .

$$l(x, \tau) = \mathcal{L}^{-1}[L(x, s)] = \int_{\tilde{N}(\tau)}^{\infty} A(x, y)[1 - e^{-(r+\lambda)(\tau-M(y))}]dy \tag{A.26}$$

where  $\tilde{N}(\tau) = \frac{e^{-2\rho\tau}}{1-e^{-2\rho\tau}}$ .

Thus, the solution to our original PDE (A.12) is  $u(x, t) = l(x, T - t)$ . So

$$u(x, t) = \frac{\sigma}{4(r+\lambda)\sqrt{\pi\rho}} \int_{N(t)}^{\infty} e^{-\frac{\rho}{\sigma^2}x^2y} y^{\frac{r-2\rho}{2\rho}} (1+y)^{-\frac{r+\rho}{2\rho}} [1 - e^{-(r+\lambda)(T-t-M(y))}]dy \tag{A.27}$$

where  $x < 0, 0 \leq t \leq T$ ,  $N(t) = \frac{e^{-2\rho(T-t)}}{1-e^{-2\rho(T-t)}}$  and  $M(y) = \frac{1}{2\rho} \ln(1 + \frac{1}{y})$ . ■

### A.5. Proof of Theorem 2

#### Proof.

First, we prove  $u_t(x, t) < 0$ . Since

$$u(x, t) = \int_{N(t)}^{\infty} A(x, y)[1 - e^{-(r+\lambda)(T-t-M(y))}]dy, \tag{A.28}$$

where  $A(x, y) = \frac{\sigma}{4(r+\lambda)\sqrt{\pi\rho}} e^{-\frac{\rho}{\sigma^2}x^2y} y^{\frac{r-2\rho}{2\rho}} (1+y)^{-\frac{r+\rho}{2\rho}}$ ,  $N(t) = \frac{e^{-2\rho(T-t)}}{1-e^{-2\rho(T-t)}}$ , and  $M(y) = \frac{1}{2\rho} \ln(1 + \frac{1}{y})$ , we have:

$$u_t(x, t) = -A(x, N(t))[1 - e^{-(r+\lambda)(T-t-M[N(t)])}] \frac{dN(t)}{dt} - \int_{N(t)}^{\infty} A(x, y)(r+\lambda)e^{-(r+\lambda)(T-t-M(y))} dy. \tag{A.29}$$

where  $A(x, N(t))[1 - e^{-(r+\lambda)(T-t-M[N(t)])}] \frac{dN(t)}{dt} = 0$  because  $M[N(t)] = T - t$ . The integral  $\int_{N(t)}^{\infty} A(x, y)(r+\lambda)e^{-(r+\lambda)(T-t-M(y))} dy$  is positive, because:

$$(r+\lambda)e^{-(r+\lambda)(T-t-M(y))} > 0 \tag{A.30}$$

by definition and when  $y > N(t)$ , we have  $A(x, y) > 0$ . Thus  $u_t(x, t) < 0$ .

Since

$$q(x, t) = \begin{cases} \frac{x}{r+\lambda}(1 - e^{-(r+\lambda)(T-t)}) + u(-x, t) & x \geq 0 \\ u(x, t) & x < 0. \end{cases} \tag{A.31}$$

We know that:

$$q_t(x, t) = \begin{cases} -xe^{-(r+\lambda)(T-t)} + u_t(-x, t) & x \geq 0 \\ u_t(x, t) & x < 0. \end{cases} \tag{A.32}$$

Thus,  $q_t(x, t) < 0$ .

On the other hand,

$$q(x, T) = \begin{cases} u(-x, T) & x \geq 0 \\ u(x, T) & x < 0. \end{cases} \tag{A.33}$$

Thus,  $q(x, T) = 0$  because  $u(x, T) = 0$ . ■

### A.6. Proof of Theorem 3

**Proof.** Since  $x \leq 0$ ,

$$\bar{q}(t) = \int_{-\infty}^0 u(x, t) \cdot w(x)dx, \tag{A.34}$$

where, according to Eq. (24),

$$w(x)dx = 2 \cdot \frac{1}{\eta\sqrt{2\pi}} \cdot e^{-\frac{x^2}{2\eta^2}} dx \tag{A.35}$$

with  $\eta^2 = \frac{\sigma^2}{2\rho}$  and

$$u(x, t) = \frac{\sigma}{4(r+\lambda)\sqrt{\pi\rho}} \int_{N(t)}^{\infty} e^{-\frac{\rho}{\sigma^2}x^2y} y^{\frac{r-2\rho}{2\rho}} (1+y)^{-\frac{r+\rho}{2\rho}} [1 - e^{-(r+\lambda)(T-t-M(y))}]dy, \tag{A.36}$$

where  $N(t) = \frac{e^{-2\rho(T-t)}}{1-e^{-2\rho(T-t)}}$ ,  $M(y) = \frac{1}{2\rho} \ln(1 + \frac{1}{y})$ ,  $x < 0$  and  $0 \leq t \leq T$  according to Theorem 1.

In  $u(x, t)$ , the only term containing  $x$  is  $e^{-\frac{\rho}{\sigma^2}x^2y}$ . Let  $\phi = \frac{\eta}{\sqrt{1+y}}$ , then:

$$\int_{-\infty}^0 e^{-\frac{\rho}{\sigma^2}x^2y} \cdot w(x)dx = (1+y)^{-\frac{1}{2}} \cdot \frac{2}{\phi\sqrt{2\pi}} \int_{-\infty}^0 e^{-\frac{x^2}{2\phi^2}} dx = (1+y)^{-\frac{1}{2}}. \tag{A.37}$$

With the term containing  $x$  integrated,

$$\bar{p}(t) = \frac{\sigma}{4(r+\lambda)\sqrt{\pi\rho}} \int_{N(t)}^{\infty} (1+y)^{-\frac{1}{2}} y^{\frac{r-2\rho}{2\rho}} (1+y)^{-\frac{r+\rho}{2\rho}} [1 - e^{-(r+\lambda)(T-t-M(y))}] dy. \tag{A.38}$$

Plugging  $M(y) = \frac{1}{2\rho} \ln(1 + \frac{1}{y})$  into this equation and reorganizing the terms,

$$\bar{p}(t) = \frac{\sigma}{4(r+\lambda)\sqrt{\pi\rho}} \left[ \int_{N(t)}^{\infty} y^{\frac{r}{2\rho}-1} (1+y)^{-\frac{r}{2\rho}-1} dy - e^{-(r+\lambda)(T-t)} \int_{N(t)}^{\infty} y^{-\frac{\lambda}{2\rho}-1} (1+y)^{\frac{\lambda}{2\rho}-1} dy \right]. \tag{A.39}$$

With the integration formula  $\int y^{a-1}(1+y)^{-a-1} dy = \frac{1}{a} y^a(1+y)^{-a}$ ,  $\bar{p}(t)$  can be simplified as:

$$\bar{p}(t) = \frac{\sigma}{4(r+\lambda)\sqrt{\pi\rho}} \left[ \frac{2\rho}{r} y^{\frac{r}{2\rho}} (1+y)^{-\frac{r}{2\rho}} + e^{-(r+\lambda)(T-t)} \frac{2\rho}{\lambda} y^{-\frac{\lambda}{2\rho}} (1+y)^{\frac{\lambda}{2\rho}} \right] \Big|_{N(t)}^{\infty}. \tag{A.40}$$

Plugging  $N(t) = \frac{e^{-2\rho(T-t)}}{1-e^{-2\rho(T-t)}}$  into this equation and reorganizing the terms,

$$\bar{q}(t) = \frac{\sigma\sqrt{\rho}}{2\lambda\sqrt{\pi}} \left[ \frac{1}{r} (1 - e^{-r(T-t)}) - \frac{1}{r+\lambda} (1 - e^{-(r+\lambda)(T-t)}) \right]. \quad \blacksquare \tag{A.41}$$

### A.7. Proof of Theorem 4

#### Proof.

Based on the equation of  $\bar{q}(t)$ , we have:

$$\frac{d\bar{p}(t)}{dt} = -\frac{\sigma\sqrt{\rho}}{2\lambda\sqrt{\pi}} e^{-r(T-t)} [1 - e^{-\lambda(T-t)}] < 0 \tag{A.42}$$

since all the parameters are positive and  $0 \leq t \leq T$ .

It is also easy to verify that  $\bar{q}(T) = 0$ . Thus, the bubble shrinks and vanishes at the end of the ban.

Since:

$$\frac{d^2\bar{p}(t)}{dt^2} = -\frac{\sigma\sqrt{\rho}}{2\lambda\sqrt{\pi}} [r - (r+\lambda)e^{-\lambda(T-t)}] e^{-r(T-t)}. \tag{A.43}$$

Letting  $\frac{d^2\bar{p}(t)}{dt^2} = 0$ , one can solve for the inflection point  $t^* = T - \tau^*$ , where  $\tau^* = \frac{1}{\lambda} \ln(1 + \frac{\lambda}{r})$ .

The size of the bubble at the inflection point is  $\bar{p}(t^*) = \frac{\sigma\sqrt{\rho}}{2r(r+\lambda)\sqrt{\pi}} [1 - (\frac{r}{r+\lambda})^{\frac{r}{\lambda}} \frac{2r+\lambda}{r+\lambda}]$ .

The decreasing speed at the inflection point is  $\frac{d\bar{p}(t)}{dt} \Big|_{t=t^*} = \frac{-\sigma\sqrt{\rho}}{2(r+\lambda)\sqrt{\pi}} (\frac{r}{r+\lambda})^{\frac{r}{\lambda}}$ .  $\blacksquare$
